INTRATRACHEAL INSUFFLATION *

S. J. MELTZER, M.D.
NEW YORK

The essentials of the method of intratracheal insufflation consist, (1) in the introduction deep into the trachea of a flexible elastic tube, the diameter of which has to be much smaller than the lumen of the trachea, and, (2) the driving through this tube of a nearly continuous stream of air which returns through the space between the tube and the walls of the trachea. The distinguishing features of this method consist in the following two new principles: 1. By bringing the pure air directly to the larger bronchi, and by driving out the vitiated air from these bronchi through the force of the returning air stream, that part of the "death space" is eliminated which is represented by the mouth, pharynx, larynx and trachea. The chief aim of the complicated nervous and muscular mechanisms of respiration is to establish an efficient ventilation, capable of overcoming the obstacles offered by the mentioned "death space." A well-arranged intratracheal insufflation is fully capable of relieving and substituting the normal respiratory mechanism. 2. The practically continuous recurrent air stream prevents the invasion of indifferent or infectious foreign matter from the pharynx into the trachea.

The usefulness of the method is at least threefold. 1. It is capable, as stated before, of keeping up an efficient respiration in cases in which the normal mechanism of the external respiration fails. 2. It overcomes efficiently and conveniently the difficulties presented by double pneumothorax. 3. It offers a safe and reliable method for anesthesia, especially for the administration of ether.

In the course of the last two years, since the first publication by Dr. Auer and myself on "Continuous Respiration Without Respiratory Movements,"[1] several hundred experiments were carried out in our department at the Rockefeller Institute on the various phases and relations of the method of intratracheal insufflation. In the very short time at my disposal, I shall confine myself to brief reports and considerations of the more practical results of several series of investigations.

THE INNOCUOUSNESS OF THE METHOD

We shall deal first with the question whether any injury can be done to the respiratory organs by the use of intratracheal insufflation, as was urged, on purely theoretical grounds, by critics of this method. We devoted a good deal of attention to this point. The following results give, I believe, an unmistakable answer.

1. The method was practiced in a very large number of experiments, in most of them the insufflation lasted for many hours, and in some as long as twelve hours. In not a single case did bronchitis or pneumonia develop which had to be ascribed to the preceding insufflation. Pulmonary affections are not a rare occurrence in dogs, especially in stray animals. Nevertheless the dogs which were subject to insufflation did not show a greater disposition toward respiratory affections than animals which were not exposed to such treatment.

2. In two systematic series of experiments carried out by Dr. Githens and myself the question of aspiration was studied by means of severe tests. In one series after filling up the stomach with acid solutions, vomiting was produced by hypodermic injections of apomorphin. The vomited material was left in the mouth and pharynx for a long period during the insufflation. In another series mouth and pharynx were filled with a suspension of powdered charcoal. The animals were kept during this period under deep or light ether anesthesia. In not a single case in which insufflation was practiced was vomited matter or some of the charcoal found in the trachea or bronchi. On the other hand, when a tube was in the trachea, but no air was driven through the intratracheal tube, and the condition, therefore, was, to a degree, similar to Kuhn's method of peroral intubation, the contents of the mouth and pharynx often came out through the free end of the tube. Furthermore, when deep anesthesia was induced, in these latter experiments, especially in the experiments with charcoal, the animals died in a few minutes, and at the autopsy trachea and bronchi were found to be loaded with charcoal. When the animal was only lightly anesthetized, so that the deglutition reflex remained active, rapid swallowing seemed to clear away most of the foreign material present in the pharynx. These parallel experiments demonstrate with great distinctness the efficiency and importance of the recurrent air-stream in the insufflation method.

3. In an investigation carried out by Dr. Lamar and myself we succeeded, in a large number of experiments on dogs, to produce lobar pneumonia in every instance, with a mortality of over 15 per cent. Employing now the same method, Dr. Githens and I produced lobar pneumonia in a series of nine dogs and subsequently practiced insufflation on them for one hour every day for eight to ten days. Not a single animal of this series succumbed to pneumonia. These latter experiments certainly show that insufflation brings no greater danger to the respiratory organs even when the animals are already afflicted with such a serious but not intensely fatal disease as lobar pneumonia.

All our various extensive experiences, therefore, demonstrate conclusively that the method of intratracheal insufflation, far from being a menace to the respiratory organs, is rather capable of protecting them against injurious invasions of foreign matter.

INSUFFLATION, DIFFERENTIAL PRESSURE AND THE FACTORS OF SAFETY

Significant is the following consideration of intratracheal insufflation as a method to overcome the dangers of pneumothorax. Some surgical writers see in the intratracheal insufflation nothing more than a modification of the Brauer, or the overpressure, method; neither do they anticipate that it is capable of accomplishing more than that method. This view is based on an unfamiliarity with the essential principles of either of the methods and is entirely erroneous. The methods of overpressure as well as that of underpressure aim only at keeping the lungs distended, but do not provide for any ventilation of the lungs. This is left, as in the normal animals, entirely to the activity of the respiratory muscles. It is fundamentally different, however, with the method of intratracheal insufflation; if it is properly adjusted, it is able to carry on the process of ventilation with complete efficiency, without any aid of the respiratory mechanism. This difference is a vital point, which, however, is imperfectly understood by the workers in this line. Our own attention was directed to the importance of this difference by some striking results obtained by Dr. Auer and myself in a series of experiments in which the Brauer method and the method of intratracheal insufflation were compared. In these experiments after both pleural cavities were kept widely open for one hour or an hour and a half, both lower lobes of the lungs were removed from their approximation to the diaphragm and the posterior walls. *When using the Brauer method the animals died in a short time, often in two or three minutes.* Furthermore, the replacing of the lobes and even the starting of proper artificial respiration could not, in many, if not in most cases, restore the activity of the heart. In the insufflation method, on the other hand, even a fairly complete lifting out of the lungs from the thoracic cavity never interferes with the activity of the heart. A further difference in the behavior of the heart could be observed, when the pressure keeping up the inflation or the insufflation was discontinued and the lungs permitted to collapse. *In the Brauer method, within a few seconds after the discontinuation, the heart becomes slow and is liable to stop in less than half a minute;* while under the insufflation method a minute and a half and even two minutes may pass before the effects of asphyxia will show themselves. The same difference is manifest in the readiness with which the heart recuperates after the pressure is restored again. What is the cause of this difference?

To my mind the difference consists in the unquestionable fact that *in the Brauer method the respiratory process is frequently deprived of nearly all of its factors of safety,* while in the method of the intratracheal insufflation none is missing. The question of the preservation of the factors of safety is such an important requirement in many fields of surgical activity that I shall try to explain its meaning a little more fully. A few years ago, in a Harvey lecture, I showed that the various mechanisms of the animal body are, like human-made machines, well provided with factors of safety. When a bridge, a building or a machine is constructed, it is built, in the first place, to be able to resist the expected maximum of stress or to accomplish the expected maximum of work. Beside this provision still further powers of resistance are added to the structure, or dynamic efficiency is added to the machine, in order to meet unexpected exigencies. These additions are termed *factors of safety;* they may consist of fourfold units or of tenfold, twentyfold, etc., according to the object for which the structures or the machine are built.

In the animal body we find that the kidneys have functional substance more than twice, the liver four times, the thyroids six times, the pancreas at least ten times more than is absolutely necessary. To come to the point under discussion, the normal respiratory mechanism provides for an exchange of gases to a much greater extent than is absolutely indispensable for the maintenance of life—it is provided, as we say, with a large number of factors of safety. How large they are, we may get an idea when we analyze the conditions prevailing in the Sauerbruch or in the Brauer methods. As stated before, in both methods the actual respiration is accomplished by the contraction of the respiratory muscles. By the inspiratory distention of the thoracic cavity, and the decrease of pressure therein, air is made to rush into it, to make up the deficit. In normal animals the air can rush in only through the trachea; in animals with open thorax, however, air may rush in also through the opening in the wall of the thorax. The same is true also of the expiration, the movements of the air being only in the reverse direction. Now since the opening in the thoracic wall during an intrathoracic operation is by far much larger than the lumen of the trachea or that of the glottis, it is evident that only a very small fraction of the air enters and leaves the tracheal path during inspiration and expiration. That fraction of a respiration is surely too small to maintain life even for a short time. However, we may assume that even under these circumstances air rushes through the trachea into the lowest and most posterior part of the lungs, by the virtue of their close approximation to the respiratory muscles, more readily than through the artificial opening in the thoracic walls. These parts of the lungs, when in normal position, contribute therefore essentially to the maintenance of life under these precarious circumstances; hence the fatal effects of the separation of the posterior lobes from their natural approximation. But, whatever the mechanism may be, it is evident that the total sum of the various contributions to the exchange of air in the methods of differential pressures can be only a small fraction of the exchange which takes place in normal conditions. Nevertheless this fraction is frequently sufficient to keep up the life of the animal for a long time, to keep it up during an operation which may last for several hours.

This shows that the exchange of gases in the normal external respiration is many times more extensive than is necessary for the immediate maintenance of life; in other words, the normal function of the external respiration is provided with many factors of safety. But it shows also that under differential pressure the external respiration is frequently deprived of most of its factors of safety. What is said of the external respiration applies also to the internal respiration, and we may therefore say that in operations under the Sauerbruch or the Brauer methods the nerve cells of the medulla and the muscle fibers of the heart continue to functionate under a minimum exchange of gases. But we must remember that these structures are very sensitive tissues. Normally their activity is protected against any mishap by a great many factors of safety, by an abundance of gaseous exchange. When they persist on a minimum, they are continually on a danger line; the slightest mishap may affect the minimum, and the life of these sensitive structures is extinguished, and what is worse a subsequent abundant supply of internal respiration frequently fails to resuscitate them—artificial respiration fails to resuscitate the animal which was exposed for a long time to the dangers of a minimum respiration.

And here is the general significance of the preservation of the factors of safety during a surgical procedure. Life may seem to continue satisfactorily without the factors of safety as well as with them. But when persisting only on a minimum, life is continually on the borderline of danger; any small accident may destroy it beyond recall. With an abundance of factors *of safety small incidents leave no impression, and when* a stronger mishap occurs, proper means, early applied, bring recovery—the controlling sensitive tissues are still in a recoverable state. This applies to many surgical conditions. In intrathoracic surgery, under differential pressure, external and internal respiratory processes are deprived of most of their factors of safety, the life of the medulla and of the heart persists throughout the operation on a minimum of the gaseous metabolism. If the operation is terminated without an incident the individual may recover without manifesting any sign that it ever was in danger. If, however, some mishap occurs, be it ever so small, that minimum of internal respiration may become extinguished and life be gone beyond recovery. When this occurs, and it has occurred, surgeons ascribe the fatal result to a vagus effect, a reflex shock and what not else. But the mishap, whatever it may have been, was only the accidental terminal cause; the real cause of the fatal result is to be found in the fact that the life of the patient, under differential pressure, persisted too long on a minimum supply of internal respiration, and medulla and heart lost all their power of resistance. The addition of appliances for artificial respiration to differential chambers will frequently fail to mend the evil; artificial external respiration, and be it ever so efficient, often will not restore the life of the sensitive nerve cells and the heart muscle fibers which, after being exposed for a long time to a mere minimum of internal respiration, lost all their recuperating power.

Summing up in a few words: Under even the best-arranged differential pressure methods, the life of patients with a double pneumothorax persists on a greatly reduced supply of external and internal respiration and is continually exposed to the dangers which may result from it; under properly arranged intratracheal insufflation, however, the patient is supplied with an abundance of external and internal respiration and is at no time in danger from this source.

ANESTHESIA BY INTRATRACHEAL INSUFFLATION

In my first paper[2] on the method of intratracheal insufflation about fifteen months ago my statement with regard to anesthesia read as follows: "On the basis of my observations and experiments it seems to me that the giving of ether by the method of intratracheal insufflation is the safest and the most effective way of administration of this anesthetic." Since making this statement we had considerable experience with the administration of ether by the *insufflation method. We used* and use it daily, and for all kinds of experimental operations; it is the routine method of anesthesia in our laboratory. And I am willing to state now, and even with greater emphasis than before, that it is the ideal method of administration of ether anesthesia. If properly adjusted and supervised the anesthesia may last for many hours, without the occurrence of serious incidents during the anesthesia or of serious consequences subsequent to it. Eight dogs were kept for twelve hours continuously under profound anesthesia; there were no disturbing incidents during the anesthesia and none subsequent to it. Even in these prolonged anesthesias the animal recovered from them in less than half an hour.

In the numerous experiments of Shaklee and of Githens on the treatment of strychnin poisoning by insufflation, the animals were kept continuously under profound anesthesia for many hours, sometimes as long *as eight. The anesthesia by the insufflation method is* far superior in many respects to that of the usual method of administration of ether. It is much safer, the anesthesia is much more readily controlled; the animal gets under it more quickly when the ether is turned on and gets more quickly out of the anesthesia when the ether is turned off; it requires only scant supervision, and not much ether is used up. The method offers also the great safety that efficient artificial respiration may be immediately instituted at the first appearance of dangerous or even only of doubtful symptoms, and this merely by turning of a screw clamp or a stopcock. The effects of anesthesia disappear very rapidly and especially so, when after interruption of the anesthesia pure air is insufflated for a few minutes before the removal of the tube.

Of the various studies which we carried on regarding the relation of the insufflation anesthesia to blood-pressure, respiration, etc., I shall mention here very briefly only a few facts. In the first place I wish to make a correction. In my first paper I stated that I did not succeed in killing dogs with ether, when administered by the insufflation method. In recent studies of Dr. Githens and myself on the influence of the anesthesia on blood-pressure and respiration, we found that under certain conditions ether might become fatal even when administered by insufflation. These studies brought to light instructive results. When an animal is brought under the influence of anesthesia under conditions which are just sufficient to make the anesthesia complete, for instance under an insufflation pressure of 30 or 40 mm. of mercury and with an air stream going three-fourths through a bottle containing ether and one-fourth as pure air, the animal will remain in the same excellent state of blood-pressure, respiration, etc., as long as the external conditions remain the same. However, if the conditions change, for instance, if the entire air stream passes through the ether bottle, we may see now the blood-pressure starting to go down, its various undulations gradually disappearing, and the respiration becoming more and more shallow and slow, until it completely ceases. Even then the heart continues to beat regularly and effectively, although the pulse pressure is usually somewhat decreased. If this state is permitted to continue for an hour or longer, the animal cannot be saved any more. However, if twenty or thirty minutes after the spontaneous respiration ceased the former conditions are restored, or still better, the insufflation of entirely pure air is instituted, the blood-pressure begins to rise and the respiration begins to make its appearance, until in a comparatively short time normal and safe conditions prevail again. In these experiments a strong overdose of ether paralyzes first the functions of the medulla and much later that of the heart. Of course these were severe experimental tests and cannot and should not occur in human surgery. Here it should be the rule to reduce the ether as soon as the respiration becomes shallow and slow.

---

[2] Meltzer, S. J.: Med. Record, lxxvii, 477, 1910.

Of the further remarks which I wish to make and which of necessity will have to be extremely brief and aphoristic I shall mention in the first place the important fact that if the intratracheal tube is only of moderate size, the insufflation pressure can be increased considerably without causing any injury whatsoever. Under these conditions *an increase of 30 mm. of mercury in the external pressure may mean an increase of only 1 millimeter within the bronchi.* The increase of pressure will often prove beneficial when the patient shows some cyanosis; the tube might in this case be too small. The increase of pressure might prove useful also in facilitating the anesthesia in very resistant individuals. Such an individual resistance to ether occurs also among animals, but not with that frequency and to that degree as it may be met with in human beings with their goodly number of neurotics and alcoholics. The higher external pressure is the means of driving into the bronchi a larger quantity of ether (and air) in a unit of time. A similar result may be obtained by frequently exerting a slight pressure on the larynx for a second or two; this brings a greater distention of the lungs with all the advantages which are to be derived from it. I may mention here also the facts that the anesthesia is more rapid and more effective, the larger the bottle is which contains the ether and the more ether it contains.

Our studies of chloroform are, so far, not so extensive as those of ether, but we know already a few things about it which ought to be mentioned here. Prolonged anesthesia by chloroform led sometimes to hyperemia and even to inflammation of the lungs. Furthermore, chloroform anesthesia requires careful supervision; it affects readily the functions of the medulla. However, with proper supervision chloroform may be used for shorter operations with perfect confidence and it may be readily employed especially in individuals resistant to ether, at least for the purpose of the induction of the anesthesia.

In using insufflation in human surgery, whether for the purpose of anesthesia or for intrathoracic operations, it ought to be the rule that the continuous air stream should be interrupted five or six times per minute for one or two seconds at a time. From extensive experience we know that these short interruptions, which do not admit any aspiration, constitute a very valuable factor, a factor of safety, in making insufflation safe and efficient. The interruptions help also in recognizing the degree of the distention of the thorax. If the distention is too strong, it is due to too high an external insufflation pressure, which is easily remedied. or the tube is too large. In the latter case, no time should be lost in exchanging the tube for a smaller one. Too little distention is due to the comparative smallness of the tube. In this case, it is not always necessary to exchange the tube for a larger one. Increase in insufflation pressure, which should be done not too abruptly, will frequently remedy the deficiency. In addition, a momentary pressure on the trachea, frequently exercised, does excellent service. The pressure, however, is best applied to the larynx where a slight pressure causes a sufficient distention of the lungs.

The tube must possess a certain degree of rigidity and elasticity. However, care must be exercised in the introduction of the tube. By the use of undue force an abrasion of the mucous membranes of the larynx or trachea might occur, which could lead to a serious emphysema. For human beings the best method of introduction is apparently the one which is now being used by Dr. Elsberg, that is under the guidance of a Jackson direct laryngoscope. I shall not dwell on the methods for providing a continuous air stream and for regulating the anesthesia; they are simple mechanical problems which will be solved variously according to the bent of mind of the various surgeons. The simplest method is the one which I suggested some time ago and which consists of foot bellows for the generation of pressure and of a Wolff's bottle, branching rubber tubings and screw clamps for regulating the anesthesia. In our laboratory we employ a respiration apparatus, which provides pressure for insufflation for several animals at the same time. For human surgery, Elsberg's compact apparatus is surely the best; it was developed with ingenuity and foresight and it works with simplicity and perfection.

I shall add yet the remark that under exceptional circumstances air enters through the esophagus into the stomach. Under these circumstances a stomach-tube, which is easily introduced and which does not interfere in the slightest with the insufflation, remedies promptly this insignificant complication.

Finally I may be permitted to quote here from reports on the use of *insufflation anesthesia in human beings* kindly furnished me by Dr. Charles A. Elsberg of the Mount Sinai Hospital of New York and Dr. Charles H. Peck of the Roosevelt Hospital of New York. Dr. Elsberg, who was the first man to introduce intratracheal insufflation into human surgery and who worked on that problem with ingenuity, scientific enthusiasm and perseverance, used this method in over 125 cases; of these, ten were thoracotomies. There were no pulmonary, bronchial or laryngeal complications. Postoperative vomiting occurred only in four cases. In three cases there was some abdominal rigidity. "All the patients awoke very quickly from the anesthesia and were remarkably comfortable afterward." Dr. Peck, who is surely an unbiassed observer, began to employ insufflation anesthesia, by means of Elsberg's apparatus, about April 21, and reports now (June 7) on thirty-two cases. In twenty-eight cases, he writes, "the anesthesia was ideal; the color was perfect throughout and the respiratory movements quiet and regular." "In four alcoholic males there was some difficulty in keeping the patient quiet and relaxed, not enough, however, to seriously interfere with the operation in any case." "The recovery from the anesthesia has been very quick and quiet with less stupor and discomfort than usual." "None of the cases had postoperative hoarseness, bronchitis or pneumonia or any other postoperative complication which could be attributed to the anesthesia. I have been much struck by the absence of ether shock or depression, especially in the old and the feeble patients." The oldest patient was 74 and the youngest 10 years old. Some of the operations lasted three hours: One patient with perforated duodenal ulcer with peritonitis "vomited profusely during the operation without interfering with the anesthesia in the least or aspirating any of the vomitus." "Twenty-three of the patients had no postoperative vomiting, four vomited once very little, three vomited a few times and two had more prolonged and persistent vomiting, one being a three-hour operation on the glands of the neck and one a case of intestinal obstruction with profuse vomiting, both before and after the operation." Both Elsberg and Peck say that in operations on mouth, pharynx, superior maxilla, etc., "the method was ideal in preventing aspiration of blood and mucus, and securing perfect quiet anesthesia without difficulty." Both point out the value in many cases of having the anesthetist out of the operator's way and "that it is much easier to guard against contamination of the operative field." Dr. Peck sums up by saying: "I have seen no ill effects of any kind from the method, and while my experience is still limited, I am convinced that it has many advantages in a variety of conditions, in addition to its special use for thoracic operations."

Sixty-Sixth Street and Avenue A.

TREATMENT OF LOCALIZED APPENDICULAR ABSCESS *

VAN BUREN KNOTT, M.D.
SIOUX CITY, IA.

In a paper[1] read before this Section at the St. Louis meeting last year, Dr. Archibald Maclaren very kindly referred to an article of mine dealing with this subject. Since that time many inquiries have been received concerning the matter, and I have decided to bring the subject before the Section at this time, giving, as briefly as possible, the results of increased experience with the method.

No attempt will be made in this paper to consider the treatment of appendicitis in detail nor will any effort be directed toward the spell-binding oratory so frequently indulged in before this Section, in an effort to fix for all time and all persons, the exact moment most favorable for operation. It is my intention to confine these few remarks to consideration of the question, Should or should we not remove the appendix in practically every case of localized appendicular abscess?

In perusing the literature on this question, or in attendance at the various surgical clinics throughout the country, we find, as probably the most frequently employed plan, the removal of the appendix when it presents itself freely within the confines of the abscess, while in those cases in which it is adherent and buried by the intestinal coils, the operation is limited to simple incision and drainage, leaving the appendix to be removed at some future time. The reason given for the latter course is usually that it is unsafe to separate the adhesions forming the boundary of the abscess, thereby liberating, during the search for the appendix, pus and septic material into the uncontaminated areas of the peritoneum.

This was the course usually employed by me until *some three years ago. During the past three years* I have operated on 283 cases of appendicular abscess, sharply localized. This list does not include any case in which at operation the general peritoneal cavity was found to be infected, nor those cases of gangrene of the appendix without the formation of a distinct peri-appendicular abscess.

In this series of cases the appendix was removed in every instance at the first operation whether it could be easily detected within the abscess cavity or whether deeply buried by adhesions. In these 283 cases there occurred three deaths. One patient, a little girl, aged 4, died thirty-six hours after operation; another, a man aged 49, died sixteen days after operation from cardiac thrombosis; and the third, a boy aged 17, died four days following operation from septicemia. There were no deaths from peritonitis.

The ages of the patients included in this series ranged from 10 months to 84 years. The latter case, an old man referred by Dr. Oliver Fisher of Sloan, Iowa, had a large abscess due to a perforated appendix, and is the oldest patient suffering with appendicitis seen by me in an experience of over 3,000 cases operated on.

These results are infinitely better than those I secured under the former plan of treatment in which the appendix was allowed to remain undisturbed in a large proportion of cases.

Since the adoption of the Fowler position and drainage of the peritoneal cavity by means of a large rubber tube inserted to the bottom of the recto-vesical pouch, or cul-de-sac, supplemented by saline proctoclysis, peritonitis has been shorn of its terrors.

It was noticed in those cases of diffuse septic peritonitis due to perforation of the appendix which were treated in this manner, that convalescence was almost uniformly rapid and smooth and without distressing sequelæ. In fact, it soon became a matter of common observation that those patients whose appendices had been removed and in whom the above method of drainage was employed, recovered more rapidly and more frequently than those with localized abscess, which had been merely opened and drained. If, then, we are no longer afraid of diffuse septic peritonitis, why should we hesitate to remove the appendix in all cases? Such considerations later led to the gradual adoption of the plan of systematic removal of the appendix in abscess cases.

As experience in the treatment of these cases increased and the appendix was removed with increasing frequency at the first operation, it was noticed that during search for and removal of the appendix, small pus collections were frequently encountered here and there among the adherent coils of intestine and omentum whose presence had not been suspected, and which would have been overlooked had not the adhesions been separated. Drainage of the larger pus collection would not have reached these smaller hidden septic foci.

It was also noted that in many cases of peri-appendicular abscess which were tightly walled off, even at times high in the pelvis, separation of the adhesions would reveal a large amount of pus or purulent serum in the recto-vesical pouch or cul-de-sac, which would most certainly have been otherwise overlooked. Thus were exposed the reasons for many a secondary operation for so-called secondary abscess.

The free separation of adhesions during the removal of the appendix tends greatly to lessen the danger of postoperative obstruction, which does not occur with nearly the same frequency in cases so treated as in those cases which are merely subjected to incision and drainage of the abscess. The separation of adhesions and the establishing of free communication between the region of the cecum and appendix, formerly occupied by the abscess cavity, and the lowermost pelvic peritoneal fold (the recto-vesical pouch in males, the cul-de-sac in females), permits the best possible drainage to be instituted by the placing of a large split rubber tube carrying a wick of iodoform gauze in the lowermost peritoneal pouch and permitting it to emerge through the lower angle of the wound. This does away with the necessity of multiple drains either of tube or gauze, and thereby lessens to no small extent the tendency to the formation of postoperative adhesions. Drainage instituted as above described removes the necessity for placing either tube or gauze in contact with the cecum at a point where its vitality has been impaired by the infectious process, and thus is lessened the occurrence of fecal fistulæ, the development of which is frequently encouraged by the ill-advised placing of such drains in contact with an already weakened and diseased cecal wall, with resulting pressure necrosis.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] The Journal A. M. A., June 25, 1910.

With the patient in Fowler's position, a large rubber tube will drain the lower peritoneal pouch much more rapidly and completely than the region immediately adjacent to the cecum can be so drained, as a tube in the latter position will be more rapidly shut in by limiting adhesions than the former; and through the influence of gravity we secure at once the collection of all septic fluids at the most dependent portion of the peritoneal sac, whence they are rapidly discharged to the surface through the tube before its capacity for drainage has been destroyed by surrounding adhesions.

Because of the rapid free drainage so secured, the tendency to postoperative sepsis manifested by hepatic abscess, pylephlebitis, subphrenic abscess, empyema, etc., is much less marked than in those cases where a leaking appendix is permitted to remain and hourly add its burden of septic and infectious material to a cavity imperfectly drained, because slowly drained, and drained for much too short a time.

The removal of the appendix at a secondary operation is frequently a very difficult procedure because of the density of the surrounding adhesions, and in the majority of instances it will be found much easier to remove it at the first operation and this should now be done rather than subject the patient to a prolonged and often serious second operation.

In my experience the necessity for a second operation following appendicitis with abscess formation in which the first operation consisted merely of incision and drainage, has been noted to arise with much greater frequency than usually stated in text-books. As nearly as I can estimate it occurs in from 25 to 30 per cent. of cases. This one fact is a strong argument in favor of the removal of the appendix at the primary operation.

A few words as to the technic of the operation: The incision is invariably made through the right rectus muscle, splitting the fibers, and the peritoneal cavity freely opened. A small gauze pack is tucked into the upper angle of the wound and so adjusted as to prevent any extravasation of pus toward the liver or diaphragm. Another small pack is tucked in toward the median line from the upper angle of the wound to the lower pelvis to prevent any extravasation toward the left. The abscess cavity is then freely opened with the fingers unless opened by the peritoneal incision, and the pus rapidly mopped up with gauze sponges. The appendix is then exposed and removed. All adhesions separating the abscess cavity from the lower pelvis are now freely separated and the pus or sero-pus, which is usually found in the lower peritoneal pouch, is rapidly mopped up with sponges. A large split rubber tube, from one-half inch to one inch in diameter and carrying a wick of iodoform gauze, is inserted through the lower angle of the wound to the bottom of the recto-vesical pouch or cul-de-sac, the protecting gauze removed and the wound closed down to the tube with interrupted, through and through silkworm sutures. Attention is called to the large size of the tube, as I believe the first hours of drainage are those which count. I had these tubes made to order in 1902, and have employed them ever since for peritoneal drainage.

The patient is then placed in bed, the head of which is elevated at least thirty inches from the floor. The patient is turned sharply on his right side and furnished with a special nurse who is instructed to see that the right-side posture is maintained for at least twenty-four hours. Proctoclysis is immediately begun and continued as long as the individual case requires. Water is allowed at once, but in small quantities. Not more than one ounce at a time and frequently repeated. Morphin is given and repeated whenever necessary to control pain. No nourishment is given for forty-eight hours and then sparingly.

The two hundred and eighty-three cases mentioned above represent but a small portion of peri-appendicular abscesses which have been so treated, as I have been working up to this point for years by gradually increasing the indications for the removal of the appendix in these cases, and they are reported merely because they represent an unbroken series of cases which have been so managed. Since 1902, many patients with diffuse septic peritonitis have been treated by the same form of drainage and increasing experience with its value when so employed seemed to justify the belief that peri-appendicular adhesions may be separated not only with impunity, but under proper precautions, even with benefit.

The method is not advocated for the occasional operator, nor is the claim advanced that it should be invariably employed by men of great experience. However, it is urged that it should be much more frequently employed by competent surgeons than is now the custom, and I believe that the instances in which it is contra-indicated should be very rare indeed.

SUBPHRENIC ABSCESS THE RESULT OF ACUTE INFLAMMATION OF THE VERMIFORM APPENDIX *

GEORGE G. ROSS, M.D.
PHILADELPHIA

It is no doubt true, as Jopson[1] has stated, that subphrenic abscess is an uncommon affection at any time of life. Nevertheless, the constantly increasing number of reported cases must be taken to mean that while the affection is uncommon it is not very rare.

Before the era of abdominal surgery, it was generally believed that subphrenic abscess most often arose from disease of the upper abdominal viscera, and that other sources of origin were rare. More extended experience with the inflammatory affections of the abdomen has demonstrated that appendicitis is one of the most frequent causes of subphrenic abscess; that such an abscess is one of the gravest complications of appendiceal disease, and that it is one of the conditions associated with appendicitis most often overlooked.

The principal points to be noted in a consideration of subphrenic abscess complicating appendicitis are:

I. The frequency and incidence as to age, sex, etc.
II. The mode of infection.
III. The anatomy of subphrenic collections arising from disease in the right iliac fossa.
IV. The symptomatology.
V. The treatment.

I. FREQUENCY

In 3,391 consecutive cases of acute appendicitis at the German Hospital, there occurred thirty cases of subphrenic abscess or 0.8 per cent.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Jopson: Arch. Pediat., 1904, xxi, No. 2.

In 500 consecutive cases of acute appendicitis in children under 14 years of age at the Mary J. Drexel Home, there was one case of subphrenic abscess, or 0.2 per cent.

In the total number of 3,891 cases of acute appendicitis in adults and children, there were thirty-one cases of subphrenic abscess, or 0.7 per cent.

Sir Frederick Treves[2] in 1,000 cases of acute appendicitis had six instances of subphrenic abscess. Kelly and Hurdon[3] quote 410 consecutive autopsies at the Boston City Hospital. Of these cases there were thirteen of subphrenic abscess, seven of which were appendiceal in origin.

Lance[4] collected the records of 943 cases of subphrenic abscess, and of these 222 were due to acute appendicitis.

Piquand[5] collected 890 cases of subphrenic abscess, and of these 191 were due to appendiceal disease.

From these statistics we may safely draw the following inferences:

1. Subphrenic abscess following appendicitis is more common than formerly was supposed.
2. It occurs in from 0.5 per cent. to 1 per cent. of all cases of acute appendicitis.

The exact ratio of subphrenic abscess due to appendicitis and cases due to other causes in our own experience at the German Hospital, I have been unable to determine, but a fairly thorough examination of the records, leads to the conclusion that appendicitis outranked all other causes combined. It is true that there were far more cases of appendicitis treated than of any other intra-abdominal condition, and the preponderance, I believe, was more marked than in most general hospitals or surgical clinics.

II. MODE OF INFECTION

The mode of infection of the subdiaphragmatic spaces from disease of the appendix has been most carefully studied. Barnard,[6] Lance,[4] and Cosentino[7] have gone into the question most thoroughly; the first from the anatomic side; the second from the clinical; and the third from the clinical and experimental sides. Their classifications and views as to the relative importance of each method of infection vary somewhat, but they agree that the infection may occur:

1. As a part of the general peritonitis—these cases are not to be included in a consideration of true localized subphrenic abscess.
2. By direct extension up the lower peritoneal fossæ.
3. Through the medium of the portal vein (Barnard and Lance). This, in our experience, is a very rare occurrence, being found in but two of twenty-one autopsies at the German Hospital in which subphrenic abscess was present.
4. By lymphatic extension (a) up the right retroperitoneal cellular tissue or (b) up the lymphatics around the deep epigastric artery to the falciform ligament. (Barnard.)

I believe that the second of these methods of approach is by far the most frequent. Cosentino also has laid especial stress on this as a result of his anatomic investigations and experiments with the course taken by various fluids when introduced into different localities in the abdominal cavity.

An interesting assertion in this connection is that of Lance,[4] that in the retroperitoneal form of infection, early operation will not prevent the subsequent formation of infected foci as a result of the extension in the cellular tissue. It is perhaps too broad a statement to make, that operation, however early, will not prevent this diffusion. But I have found that cases in which such infection takes place are among the most virulent and fatal of all cases of appendicitis and, when the retroperitoneal cellular and lymphatic tissues have been thoroughly invaded by the infectious bacteria, death from extension or toxemia is sure to occur.

Some of the French authors credit the appendix with a double lymph supply and state that the lymphatics of the appendix, in addition to draining to the glands at the ileocolic junction, have a close communication with the lymphatics of the ascending colon. If this be true it would furnish perhaps some reason for the frequency of the retroperitoneal origin of subphrenic abscess following appendicitis.

The infection of the subphrenic fossæ by the general circulation is mentioned by several authors as a theoretical possibility, but there has been no instance reported in which this seems to have been the sequence of events.

The extension by means of lymphatics about the deep and superficial epigastric arteries, is supported by one case cited by Barnard[6] and this he considers as not being definitely proven.

Lance[4] mentions as predisposing causes for the formation of a subphrenic abscess, several locations of the appendix, notably those in which the appendix runs high behind the colon, is retrocecal or retroperitoneal. It is perfectly evident that any one of these conditions must tend to render subphrenic abscess more likely.

III. ANATOMY

For all methods of formation of subdiaphragmatic collections following appendicitis, except that by means of the retrocecal retroperitoneal cellular tissue, we must find some anatomic explanation, for it would seem unlikely that infectious pus should gravitate in that direction. No better statement of the conditions favoring such an extension can be given than that of Barnard. He says:[5]

> The recent investigations of surgeons in connection with the treatment of diffuse peritonitis have shown that the main cause of subphrenic accumulation is gravitation. As a patient lies flat on his back in bed, the posterior extremity of his subphrenic spaces are only separated from the mattress by the skin, the ribs and the diaphragm, which together do not make up much more than ½ inch of tissues. The pouch of Douglas or the rectovesical pouch in the male, in a similar way are only separated from the mattress by the skin, the coccyx, and the width of the flattened rectum. Between these two dependent pouches the thick muscles and tissues of the loins, with the kidneys and the perinephric fat, rise as two elevated mounds. When the general peritoneum is infected, a profuse flow of serum is poured out, and this gravitates upward into the subphrenic spaces and downward into the pelvic pouch. If the patient is well propped on pillows or is supported by an efficient bed rest (Fowler's position) fluids will run from beneath the diaphragm over the loin mound into the pelvic pouch, from which it may be drawn off by a tube passed to the bottom of that fossa, from a puncture above the pubes. This method is effective in preventing subphrenic abscess only while the exudate is diffused. When it is shut in and localized, special measures must be adopted to evacuate it.

The French authors also lay great stress on these anatomic relations—indeed, the gutter formed by the colon and the abdominal wall on the right side is by them named the right parietocolic sinus (of Lafeyre).

The most minute and painstaking investigation of the anatomy of subphrenic abscess has been made by Bar-

nard.[6] He divides all subphrenic abscesses according to their location as regards the falciform and lateral ligaments of the liver into:

A. Intraperitoneal.
  1. Right. { I. Anterior.
             II. Posterior.
  2. Left. { III. Anterior.
             IV. Posterior.
B. Extraperitoneal. { V. Right.
                      VI. Left.

A right anterior intraperitoneal abscess is one situated between the upper surface of the right lobe of the liver and the diaphragm.

A right posterior intraperitoneal abscess is one in the subhepatic pouch, a pyramidal space bounded laterally by the abdominal parietes, in front by the liver and gall-bladder, posteriorly by the abdominal parietes and having its apex formed by the upward slope of the margin of the left lobe of the liver.

A left anterior intraperitoneal subphrenic abscess or perisplenic abscess lies in the fossa bounded by the diaphragm above, the left lobe of the liver below and to the right, and the spleen to the left. It is bounded sharply to the right by the falciform ligament. Barnard describes a fossa lying between the vertebral column, the descending colon and roofed in by the mesentery by which the fossa first described communicates with the rectovesical or recto-uterine pouch.

A left posterior intraperitoneal subphrenic abscess is one situated in the lesser peritoneal cavity.

A right extraperitoneal subphrenic abscess is one formed in the cellular space between the layers of the coronary and other peritoneal ligaments of the liver.

A left extraperitoneal subphrenic abscess is one formed in the retroperitoneal cellular tissue of the left loin.

In Barnes' experience in twelve cases of appendiceal subphrenic abscess practically all were on the right side.

I have found it impossible so closely to determine the exact anatomic variety of subphrenic abscesses as has seemed possible to some investigators. They may all be grouped into those of the right and left, anterior or posterior. The intraperitoneal or extraperitoneal origin is often impossible to determine.

Of thirty-one cases at the German Hospital:

29 were on the right side only.
1 was double right and left.
1 was on the left side only.

These figures would tend to show that in most instances the extension to a subphrenic fossa from a diseased appendix is not from an accompanying peritonitis in the pelvic basin, but arises directly from the original appendiceal focus.

Numerous isolated instances of left subphrenic abscess following appendicitis have been reported.

It is, moreover, not absolutely determined that an abscess of extraperitoneal origin cannot in every way come to assume the characteristics of one of the intraperitoneal variety.

It is to my mind a refinement of diagnosis at present impracticable of accomplishment, for any one to determine definitely the variety of subphrenic abscess before operation. As will be seen later, we are fortunate indeed always to diagnose even the existence of a subphrenic abscess.

The usual contributing factors in reference to subphrenic abscess, complicating appendicitis need not be discussed at length. The bacteriology of the complicating infection is that of the original diseased focus. The incidence as to age is identical with the range of ages in appendicitis. Statistics would seem to show that subphrenic abscess is rarer in appendicitis in children. But of eight cases from the Pennsylvania Episcopal and University Hospitals in the past two years, four occurred in patients 15 years of age and under.

Pathologically, subphrenic abscess in association with appendicitis falls into three groups:

1. Those occurring or found at operation, i. e., an immediate and primary complication of the disease.
2. Those making themselves manifest as late or postoperative sequelæ during the postoperative stadium.
3. Cases occurring a long time after the primary infection.

IV. THE SYMPTOMATOLOGY

The mode of onset of the symptoms of subphrenic abscess must vary with the time of its occurrence.

It has been my experience that when the condition has been found at the first operation, it has often been not definitely diagnosed. The diagnosis of appendicitis with abscess is made, but the definite localization of a subphrenic collection has been overlooked. This, however, is not always a matter of such grave importance, since at the operation the collection should be discovered, particularly if it be one formed by direct extension. There can be no doubt that, on the other hand, certain isolated and well walled-off abscesses which were present at the first operation, are at times overlooked. In the series of thirty-one cases at the German Hospital, there was one undoubted instance of this and probably one or two others.

The collection occurring as postoperative sequelæ are those in which our diagnostic powers are taxed to the utmost.

There may be two methods of onset: (a) sudden and (b) insidious.

Many surgeons have stated it as their experience that subphrenic abscess after appendicitis most often makes itself known quite suddenly. As regards the major symptoms this is no doubt true. Yet, it has been my experience, even in those cases in which the symptoms of the secondary collection came on with apparent suddenness, that the convalescence previously had not been entirely uneventful. It is quite true that the onset of pleural pain, high fever and delirium is sudden, but it appears more so if the previous malaise without symptoms of definite character has been more or less slighted.

Jopson[8] has particularly laid stress on this point. He says that "a moderate continuous elevation of the temperature, a pulse little if any above the normal, an entire absence of abdominal symptoms, and a physical expression of comparative comfort and well-being are to be *recognized as not inconsistent with the presence of a* subphrenic abscess."

Barnard's statement, therefore, that all of his twelve cases of appendiceal subphrenic abscess had an acute onset, must be considered as referring to the onset of local symptoms and of marked sepsis.

In giving, therefore, a list of symptoms of subphrenic abscess, I should place first sepsis following an operation for appendicitis without evidence of its cause, the primary incision progressing favorably.

---

[8] Ann. Surg., 1910, vii, 427.

Second in importance to the symptoms of general sepsis, we find the signs of pulmonary involvement at the base of the lungs. The most valuable of these indications is the presence of a more or less marked area of dulness. In addition to this, we often find the other indications of a collection in the pleural cavity, i. e., lessened breath sounds and fremitus. In several instances in the series of cases at the German Hospital, the dulness and other physical signs have been noted anteriorly, and in one case the first indication of trouble was in the left axillary space. Pleural friction sounds are at times noted as in the case last mentioned.

The exact condition of the lung and pleural space above a subphrenic abscess, is most difficult of exact determination. The dulness and changes in the resonance and fremitus are accounted for by the pressure upward on the vault of the diaphragm. But the comparative frequency of pleural friction, cough and the occasional early occurrence of râles would seem to indicate that in many instances of subdiaphragmatic abscess there is early involvement of the pleural cavities themselves, and indirectly of the lung tissue. It is fortunate that these changes give rise to empyema as rarely as they do. Of twenty-one fatal cases coming to autopsy but five showed purulent pleurisy, and one a pleurisy with exudate not purulent. Two of these five cases showed actual perforation of the diaphragm.

The abdominal symptoms of subphrenic abscess, when present, are those of any collection within the abdomen. They are the presence of a mass; pain, and tenderness; Barnard found that in thirty-three of his seventy-seven cases a mass formed by the abscess itself was noted in the abdomen. This, however, includes cases of subphrenic abscess due to all causes. In my own experience with this form of abscess following appendicitis, the proportion of cases in which there was an abdominal swelling has been decidedly less. This perhaps is due to the fact that, since the infection is oftenest by direct extension along the lumbar fossa, the abscess is most often found deep under the liver or else above it and concealed between the upper liver surface and the vault of the diaphragm. In the latter class of cases there may be some slight bulging of the chest-wall on the infected side.

The pain encountered is localized to the area of infection, but often not definitely confined to a limited area. Indeed, the pain oftenest complained of is a pleural pain. In some cases, the onset is such that a pleurisy seems primary and the subdiaphragmatic abscess secondary. Tenderness will be encountered when the abscess presents at an accessible part of the abdomen—often it is elicited only by quite deep palpation.

Needling is an important aid in localizing suspected collections of pus beneath the diaphragm, as in those above it. Barnard recommends that it be done in a most systematic and thorough way and only under complete anesthesia. With the latter provision I cannot agree. Even in the presence of pus, our attempts at aspiration may be negative and while a positive finding confirms the diagnosis, a negative by no means sets it aside.

Mention has been made of those cases of subphrenic abscess in which the onset is long delayed. Such an instance is Case 19 of this series, in which the onset of the disease occurred a year after a primary appendiceal infection. In a case reported by Ashhurst,[9] the interval was four months, and Meisel[10] has reported an instance in which there is no doubt that a subphrenic abscess occurred one and one-half years after a primary appendicitis. In these cases, the onset is usually more or less sudden. There is a sudden awaking of a long-latent infectious focus, and the event partakes oftenest of the nature of a grave abdominal catastrophe as in the instances quoted.

The diagnosis of subphrenic abscess being a matter of such considerable difficulty, it is to be expected that the differential diagnosis is one hardly definable by strict rules. Most often the differentiation is between a subdiaphragmatic and a supradiaphragmatic condition. An important guide is the history of an antecedent abdominal condition apt to give rise to a subphrenic collection, even if the two illnesses have been separated by a considerable interval of time. How difficult this distinction is may be gathered from the numerous instances Barnard cites, in which it was impossible to distinguish between the two conditions. It is a well-known fact that intrathoracic conditions may simulate almost any acute abdominal condition in their symptomatology. How probable it is, then, that a condition localized immediately beneath the pleural cavities and separated from them by but little tissue, should give rise to symptoms practically identical to those of a purulent or merely serous pleurisy!

Only the most careful study of individual cases will give us even an approach to correct diagnosis. Of the other conditions most frequently confused with subphrenic abscess, it is necessary only to mention hepatic infection following operation. The symptoms of this condition are also often overlooked. Two authors give what they consider distinguishing features. Besredka states that there is never jaundice in uncomplicated subphrenic abscess and that the fever is not so high in liver infections. Jullard states that in liver infections the leukocytosis is higher than in any other abdominal condition—a by no means infallible sign, as in isolated instances the white blood-count has been excessive also in subphrenic abscess.

How difficult may be the diagnosis of subphrenic abscess is shown by Case 31, reported from the Mary Drexel Home. In this instance the symptoms pointed to the presence of a meningitis, and lumbar puncture gave turbid fluid. Chest dulness finally developed and pus was obtained on puncture, and the subphrenic condition made itself evident.

V. TREATMENT

The treatment of subphrenic abscess following appendicitis is that of any other collection within the abdominal cavity.

It may not be out of place here to mention certain factors which may influence the formation of subphrenic abscess and which must be considered at the primary operation.

Primarily, when there is a localized collection, it is essential to explore it as to its extent and direction. When it is drained, the drainage must be sufficient.

When pelvic pus is present, the pelvis must be drained, no matter how slight the amount of fluid may be.

If there be a diffuse peritonitis, it is essential that the patient be placed in a semisitting or Fowler position to facilitate the gravitation of septic fluids away from the diaphragmatic area.

---

[9] Ashhurst: Tr. Philadelphia Acad. Surg., 1910, xiii, 154.

[10] München med. Wchnschr., 1909, lvi, 1411.

The appendix should be removed whenever possible, to prevent its acting later as a source of infection.

The operations for subphrenic abscess may be classed in three groups:

1. The Abdominal or Loin Incision: This is applicable to those cases in which there is definite pointing of the abscess either in the upper abdominal area or in the loin. It must be placed so that we can procure the maximum of exposure to the diseased area. The further procedure is that of any abdominal abscess.
2. The Subpleural Route: This incision consists of resection of the tenth rib in the midaxillary line and traversing the diaphragm below the pleural reflection.
3. The Transpleural Route: According to the probable location of the pus, one or two ribs are resected, the pleura opened and the collection evacuated through the pleural base. The only point of importance in this operation is the suturing of the two layers of the pleura after incision before opening the subdiaphragmatic abscess—this to prevent diffusion of infectious material throughout the pleural cavity.

In all of these methods of procedure there must be drainage by tubes of sufficient caliber and rigidity to insure the evacuation of all infectious fluids.

Case 1.—J. D. Death April 16, 1901. Diagnosis, acute appendicitis. Incision about 8 inches long made through the right rectus. Intestines showed evidence of diffused peritonitis. General cavity walled off with gauze; appendix found up under the liver, gangrenous and perforated. Small quantity of pus present; some pus between the diaphragm and the liver. Appendix removed.

Case 2.—J. P., aged 23. Death March 13, 1902. Diagnosis, acute appendicitis. At operation the following note made: "Secondary abscess up near the liver."

Case 3.—F. E. W., aged 16. Death July 13, 1902. Diagnosis, acute appendicitis. Incision through the right rectus muscle; appendix outer side of the cecum; gangrenous and perforated. Abscess cavity extended up underneath the liver, and there were numerous adhesions in the locality. Appendix removed. Drainage; one piece of gauze extended up as high as the liver.

Case 4.—J. G. R., aged 52. Death Dec. 13, 1902. Incision 5 inches long in the right linea semilunaris over a mass about 2 inches by 4 inches, which can be palpated under ether. Appendix found covered with a large mass of exudate to the outer side of the cecum and ascending colon. Mass extending almost to the liver margin. Fifteen days after operation, sclera yellow, tenderness over the liver, with edema over the right costal margin. Very weak. Two days later: "Liver tenderness still present." No necropsy.

Case 5.—Daniel J. S., recovery, April 30, 1904. Diagnosis, acute appendicitis. At operation the following noted: Incision 20 cm. long, along the outer border of the rectus (right); omentum found adherent to the parietal peritoneum; bowels bound together generally by numerous adhesions; general peritoneum walled off by pads and the adhesions freed in the right iliac fossa; the appendix not found in the right iliac fossa.

Then the ascending colon was freed from adhesions almost up to the liver. To the outer side of the ascending colon just below the liver, a small pocket of pus was opened. This was swabbed out and a fecal concretion was found bound up in a mass of adhesions and exudate.

Case 6.—Cora L. Recovery May 27, 1904. Diagnosis, appendiceal abscess. At operation, March 22, 1904: Incision 5 inches long through the upper right rectus; edema of the peritoneum, on opening of which a large amount of pus escaped. Intestines and the under surface of the liver protected by gauze pads. Free pus welled up from the flank. Appendix not sought for; neither was the gall-bladder. Six pieces of gauze inserted for drainage; two pieces in the flank; two pieces under the liver; and two pieces to wall off the cecum and the ascending colon.

April 11, patient had an attack of right-sided pleurisy.

May 9, the tract extending back under the skin was laid open. It was found to communicate with another tract in which a rubber tube 15 cm. long was placed. This tube extended upward, but whether above the liver could not be determined.

May 27, patient discharged. Sinus seemed to be closing from the bottom.

Case 7.—J. B. C. Death March 11, 1905. Diagnosis, acute appendicitis. At operation the appendix found high up on the cecum and beneath the right lobe of the liver. No abscess. The appendix semigangrenous.

Before operation note was made of the tenderness of palpation over the upper part of the right iliac region. Postmortem showed a feeble attempt to wall off the infected area and general peritonitis.

Case 8.—F. W., aged 23. Death April 2, 1905. Diagnosis, acute appendicitis. At operation the appendix found and removed, also abscess around it.

At second operation "peritoneum opened and adhesions found between the gall-bladder and the liver; great omentum and hepatic flexure of the colon. These adhesions were broken up and a small quantity of pus oozed from the outer and under side of the liver margin. Pus was traced and found a large abscess the size of an orange between the liver and the diaphragm which was evacuated. Drain with tube and gauze."

The patient had four operations before he died: (1) for appendicitis; (2) for subdiaphragmatic abscess; (3) gastro-enterostomy and entero-enterostomy; (4) iliosigmoidostomy for obstruction.

Case 9.—E. M., aged 26. Death April 24, 1905. Diagnosis, acute appendicitis; abscess. At post-mortem, a subphrenic abscess found.

Note from the post-mortem: "Adhesions separated and the appendix found 11.5 cm. in length pointing directly upward towards the liver and lying beneath the abscess cavity. Appendix gangrenous at the tip." On lifting up the colon and separating the adhesions a large abscess was found extending upward beneath the liver and containing about 250 c.c. of thick, yellowish pus.

Case 10.—C. F., aged 15. Death July 20, 1905. Diagnosis, acute appendicitis. Post-mortem findings: "Large abscess beneath the liver entirely walled off."

At operation the appendix had been removed and the abscess *drained*.

Case 11.—Alice H., aged 21. Death Aug. 7, 1905. Diagnosis, acute appendicitis. At post-mortem subdiaphragmatic abscess found. At operation a counter incision in the loin made for drainage. First incision was oblique. Appendix not found at operation. Two weeks after operation the patient began to expectorate pus.

Post-mortem notes: "Region of the appendix showed a plastic peritonitis. There is a large abscess between the right lobe of the liver and the diaphragm which has ruptured through the diaphragm into the right pleural cavity and then into the lung which shows septic bronchopneumonia."

Case 12.—Magdeline H., aged 32. Death Aug. 10, 1905. Diagnosis, acute appendicitis. On examination, great tenderness between McBurney's point and the right costal margin. At operation the appendix found high up beneath the liver, gangrenous at the tip and perforated. Counter-incision made in the midaxillary line to the right of the upper angle of the original incision. Just before death, tenderness noted below the liver. At post-mortem, an abscess found to the outer side of the liver.

Case 13.—Septimus A. K., aged 26, Death, 1905. Diagnosis, acute appendicitis with abscess. Appendix found pointing upward, gangrenous and perforated; foul-smelling whitish pus escaping from the abscess to the outer side of the cecum. At post-mortem a secondary abscess found beneath the liver.

Case 14.—Katharine A. Death May 1, 1905. Diagnosis, acute appendicitis, and subphrenic abscess. Noted at operation. In the examination of the patient the following note is made: Tenderness present; most marked just below the costal border, anterior axillary line, right side. At post-mortem examination a subphrenic abscess and a lobar pneumonia of the right lung found. Appendix removed; found pointing toward the liver. The appendix was gangrenous.

CASE 15.—Samuel S. Death Dec. 17, 1905. Diagnosis, acute appendicitis; subdiaphragmatic abscess found at post-mortem. On physical examination tenderness noted in the right flank No tenderness on the left side. At operation an appendiceal abscess found. Post-mortem: Perforation of the appendix at the site of the fecal concretion. Large abscess walled off and located beneath the liver and between the liver and the diaphragm. No evidence of general peritonitis. Incision through right semilunar line.

CASE 16.—Margaret P., aged 43. Recovery March 29, 1906. Diagnosis, acute appendicitis with abscess. At the first operation, the appendix removed. No mention of any subdiaphragmatic abscess. At the second operation, the incision made through the right rectus to the costal margin. Abscess evacuated outer and under surface of the liver.

CASE 17.—Thomas F. A. Death April 19, 1906. Diagnosis, acute appendicitis. At operation the appendix found postcecal, gangrenous and perforated. Free pus in the peritoneal cavity. Post-mortem note: Large purulent collection around the liver and on the left side beneath the transverse colon. General purulent peritonitis.

CASE 18.—Lena E. Recovery May 13, 1907. Diagnosis, acute appendicitis. Extraperitoneal incision. Peritoneum thickened and congested. Opening the peritoneum which bulged into the wound, large amount of free, foul-smelling pus escaped; carefully wiped out. Appendix sought for. Finger run up outside of cecum toward the liver. Large amount of free pus found here and evacuated. More pus escaped in manipulating down toward the pelvis. Appendix removed. Second operation for fecal fistula.

CASE 19.—Nicholas B, aged 19. Recovery June 23, 1907. This patient was in the hospital in March. The case was diagnosed as chronic appendicitis and the patient was operated on for that. The appendix was removed and uneventful recovery resulted.

In the history of the second admission is noted the following: "One year began having pain in the right lumbar region, coming once or twice a week, running around to the right abdomen, at times to the testicle and now it goes down the thigh. For a week after the operation, the patient was relieved but on the day of discharge he felt his old pain. Does not vomit. Never passed bloody urine; no gravel, but he claims he passed crystals. At times his urine was very dirty-looking. Makes urine twice at nights. Often has stoppage of the stream during the act. Since admission, he has had pain in the left lumbar region similar to that in the right side save not transmitted to the abdomen."

Physical examination notes the following: "Posteriorly below the angle of the right scapula is a prominence the size of the palm, tender to palpation. Spine negative. A very tender point in the midaxillary line just below the costal margin." At operation, incision over the tenth rib; resection of this rib. A large amount of bloody semipurulent material was evacuated. Origin was not discovered; seemed to come from under the surface of the right lower lobe of the liver." Patient received great relief from the operation and made a rapid uneventful recovery.

CASE 20.—Dr. V. Death March 6, 1908. Diagnosis, acute appendicitis. Began with diarrhea. Stools a bright yellow, frothy, with a little odor.

Patient vomited and was "bilious." On the day before admission he had sudden severe agonizing pain shooting from the right lumbar region around to the inguinal region and up the anterior and lateral aspect of the chest. Taking breath at this time caused severe pain. Patient had cold sweat at time of pain but no chill. Resonance was impaired over the right chest. Two inches above the normal liver dulness, there was flatness.

Post-mortem notes: Gangrenous appendix which had sloughed off. Extraperitoneal and subdiaphragmatic abscess. Extending up to the diaphragm there was a pus cavity between the right lobe of the liver and the diaphragm, which contained about 50 c.c. of yellow pus. Right diaphragmatic pleurisy. Lung showed no noteworthy changes.

CASE 21.—George F. Death Oct. 30, 1908. Diagnosis, subdiaphragmatic abscess. About one year previously the patient had an attack of acute appendicitis and was operated at another hospital. He had drainage. After the operation he was all right. He had some trouble with his stomach.

Present illness began about six weeks before with severe cramps in the abdomen which required morphin. The pain subsided and the patient had a soreness in the abdomen. He did not vomit at first but has several times since then. Did not vomit the food he had eaten but vomited a greenish fluid. Bowels were very constipated; appetite fair and patient has had no trouble in urinating.

Physical examination: Abdomen moderately distended; very rigid in the epigastrium and the left hypochondrium. In the left side in the costal margin was felt a mass on deep palpation somewhat tender and immovable. No tenderness over the gall-bladder.

Operation: Incision in the upper abdomen through the right rectus down to the peritoneum. Peritoneum opened and gall-bladder exposed. No lesion in the stomach. Stomach was lifted up and underneath the liver was evacuated an abscess containing pus and gas. Intestines packed away. Abscess evacuated and two pieces of gauze introduced. After notes: Patient developed a severe cough with a foul-smelling expectoration (purulent). Examination of the left axilla showed signs of cavity formation. Needle introduced and pus was obtained. Patient gradually became more and more septic and died.

CASE 22.—Henry M. Death June 12, 1909. Diagnosis, acute appendicitis. At first operation the appendix was removed and the abscess drained. Appendix was gangrenous and perforated. Four weeks later patient noticed a dulness in the left axillary line, beginning at the transnipple line. There was pleural friction here; absence of breath sounds over this area; no fremitus, more tender in the splenic region.

At operation: Incision over the tenth rib in the axillary line; resection of this rib (1½ inches); pleura and diaphragm perforated with the finger and a large amount (500 c.c.) bloody pus escaped coming from below the diaphragm and from around the spleen. Many recent pleural adhesions about the base. Drained, etc. Third operation ten days later. Resection of the seventh rib. At first no pus was located; later a subdiaphragmatic abscess was located and the thick yellow pus evacuated. (In the notes there is no mention of the incision being right or left but from the previous mention of the dulness in the left axilla, I presume that the two abscesses are in the left; also because the spleen is mentioned.)

CASE 23.—Oliver M., aged 17. Death July 14, 1909. Diagnosis, acute appendicitis. At operation appendix found behind the cecum. The appendix removed. Pus present. One month after operation patient was troubled with pain in the right chest with dulness and distant breath sounds for one week. Aspirated, blood but no pus. Later the patient became delirious. One week later the right chest was aspirated and pus found.

Operation: Incision over the ninth rib; part of this rib removed and about 500 c.c. of thin pus drawn off. Later 2,000 c.c. of similar fluid was removed from the cavity. Note of July 14, 1909: "No post-mortem but lesion considered to have been a subdiaphragmatic abscess with rupture into the pleura."

CASE 24.—Moritz H., aged 65. Death March 10, 1910. This patient was admitted to the medical wards, the case being diagnosed as carcinoma of the cecum. Note was made that the patient was simple-minded and did not answer questions sensibly. Patient had not been well for a couple of years, but not seemingly sick until six months previously, when a profuse diarrhea began which lasted during this illness. Patient had noticed a mass in the lower right side of his abdomen; a double direct hernia has also given him trouble. (From his daughter it was learned that he had had a definite attack of pain in the abdomen about one year ago.)

Examination: Liver dulness began at the top of the fifth rib and extended below the costal margin for a distance of 1.5 c.c. Liver was smooth and the edge was not easily palpable. In the right lower abdomen was to be felt a mass of moderate density, fixed. It did not move on deep respiration. Tympany was elicited in front of it. It was tender and painful on palpation. There was hernia on each side, not complete.

Patient died of edema of the lungs. The necropsy was performed by Dr. Kelly and the diagnosis of abscess made. At post-mortem there was found a large abscess in the region of the appendix, one around the liver and pancreas and one around the spleen, all old processes and all walled off.

Case 25.—Michael McC., aged 44. Recovery May 26, 1910. Diagnosis, acute appendicitis with abscess. At operation the abscess cavity found extending to the diaphragm; part of the tenth rib resected and the abscess drained; a loin incision made and one up right rectus; the two connected. "Abscess, found postcecal and extended to the diaphragm." Vaccine treatment helped to heal in this case.

Case 26.—Lewis E. Recovery Dec. 2, 1910. Diagnosis, acute appendicitis with abscess. At operation, appendix was found lying in thick yellow pus. The appendix removed; incision was enlarged upwards; subhepatic fossa covered with exudate. Two pieces of gauze carried to the fossa.

Case 27.—Harry H., aged 23. Death Dec. 9, 1910. Diagnosis, subdiaphragmatic abscess. Operation: (1) Straight incision. Pus found, subhepatic; (2) loin incision and pus found, subdiaphragmatic; (3) incision in the tenth interspace and much pus escaped. Appendix found retrocecal, gangrenous and perforated, extending to the subhepatic fossa; removed.

Case 28.—George E., aged 49. Death Dec. 28, 1910. Diagnosis, subdiaphragmatic abscess. Pain in the lower abdomen right side. One day's duration. Incision in the eighth interspace; resection of the ninth rib; pleural effusion. Diaphragm pierced, evacuating a subdiaphragmatic abscess. On Dec. 25, 1910, empyema tapped and 500 c.c. of foul pus drained.

Case 29.—William H. M. Recovery Dec. 28, 1910. Diagnosis, subdiaphragmatic abscess. Pain under the right costal border. Pain for two weeks in the right subdiaphragmatic region. Patient sick for four weeks. Incision in the postaxillary line and 5 c.c. of the ninth rib resected. Nothing in the pleural cavity. Diaphragm opened and pus evacuated.

Case 30.—Walter C. Recovery Jan. 15, 1911. Diagnosis, acute appendicitis. At operation a right-sided subdiaphragmatic abscess was found. Pain in the abdomen and distention. Three days' duration. No pain in the costal margin. Dulness in the upper right abdominal quadrant. Operation: loin incision; appendix gangrenous, perforated and amputated. Subdiaphragmatic abscess found and drained.

Case 31.—Emma K., aged 10. Death April 13, 1910. Family and previous medical history negative. No history of previous appendiceal attacks. Patient admitted to the Children's Hospital of the Mary J. Drexel Home on March 19, 1911. The attack began the day previous suddenly at school after eating light breakfast. Patient had severe abdominal pain and projectile vomiting. There was restlessness which passed almost immediately (in a few hours) into semiconsciousness and later complete unconsciousness. There was violent delirium. The next day the temperature rose to 104; respiration 24; pulse 128.

On admission the child was violently delirious. She was lying on the left side with her head drawn back; thighs (both) flexed on the abdomen; legs flexed on the thighs. The patient was restless and irritable. Every fifteen minutes she would have a general clonic convulsion. Meningitic cry present. The fingers were tightened into the palms during these attacks. Examination at that time showed heart and lungs negative. The abdomenal walls were rigid but not distended, and there was apparently great tenderness all over the abdomen, more marked in the right lower quadrant. Knee-jerks were absent; no ankle-clonus. Babinski and Kernig positive. Slight opisthotons. Lumbar puncture showed tension of fluid very low, 10 c.c. obtained of cloudy fluid. Examination revealed marked increase in polynuclears; no increase in albumin; 15 c.c. of Flexner's serum injected.

March 20, 1910: Day after admission. Temperature normal; child rational and comfortable; abdomen relaxed and not tender

March 21: High fever all day; temperature 105; respiration 40; pulse 130—irregular in type. Vomiting frequent; regurgitation of bile. The whole abdomen was very tender. Patient had five loose, watery, yellow stools. No rigidity of the neck. No exaggeration of knee-jerks; no clonus; right ear discharging; left tympanic membrane, red but not bulging. Was punctured by Dr. Bliss. Surgeons decided peritonitis was not present and advised against operation. Similar puncture 8:30 p. m.; 11 c.c. turbid red serum obtained; 15 c.c. antimeningitic serum injected.

March 25: Temperature again elevated; child very ill; abdomen distended and generally rigid; vomiting has ceased; bowels greenish and frequent. Spot of dulness obtained over the base of the right lung, with marked resistance to finger and consolidation was suspected. Breath sounds not increased.

March 27: Condition better; abdomen tender but soft. Tenderness more marked in upper right quadrant. Examination still showed spots of dulness in chest. Temperature 103; pulse 120; respiration 40. Dr. J. B. Deaver advised against operation when brought into consultation with Dr. Hand and Dr. H. C. Deaver.

March 29: Temperature lower, 102; respiration 44; pulse 116. Physical signs show same area of dulness.

March 31: Child's general condition seems much improved. Chest condition reveals dulness extending downward from the seventh interspace, in postaxillary line; breath sounds very distant. No edema or bulging of interspaces. Temperature 100, pulse 108, respiration 44.

April 2: Needle introduced in the eighth interspace in postaxillary line downward and forward 4 inches. Pus obtained. Child somewhat emaciated. Liver could not be palpated below costal border. Abdomen somewhat distended but no tenderness or rigidity.

April 3: Operation: Dr. H. C. Deaver made incision over the seventh rib. Diagnosis, empyema. Rib resected; the pleural cavity explored; small amount of sero-pus found; finger introduced downward through the diaphragm and a large subdiaphragmatic abscess evacuated, probably 2 pints of foul-smelling pus. Diaphragm was then stitched to the muscle and pleura, so as to isolate pleural cavity. Large drainage-tube inserted into the abscess and a tube of smaller caliber inserted into the pleural cavity. Culture of pus showed colon bacillus.

April 13: Child died suddenly after dressing of cardiac syncope. No post-mortem obtainable.

Collateral Findings.—Leukocytes varied from 28,950 on admission 3-20-10, with 96.5 per cent. polynuclears, to 14,000 with 86 per cent. polynuclears at operation, April 3, 1910.

March 28: Blood-culture sterile. Urine showed faint trace albumin; no casts. Culture showed colon bacillus. Cerebrospinal fluid showed large numbers of polynuclear cells; no micrococci.

1721 Spruce Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. ROSS AND KNOTT

Dr. Thomas W. Huntington, San Francisco: In a long experience, attended with occasional humiliations, I have arrived at this conclusion with reference to the removal of the perforated appendix at the time of the initial undertaking: First, a condition which appears simple in the beginning may involve an exercise of the highest surgical judgment and skill. Second, the question of the removal of the appendix at the time is one which can be decided only at the time. In a word, the appendix at times can be removed even though it seems to be fairly well incorporated in the abscess wall; while on another occasion to touch an appendix which is incorporated in a barrier in the wall, is to invite failure if it does not insure it. My guide in this matter has been the condition existing prior to operation. If we can be perfectly sure that we are encountering a vicious type of infection, if the patient is melting down under it, if he has deteriorated materially within the preceding twenty-four, forty-eight or seventy-two hours, I have come to regard the appendix as being governed by the principle of *noli me tangere.*

Dr. W. W. Grant, Denver: There is no more unfortunate sequel to or complication of appendicitis than the subdiaphragmatic abscess. We know no such thing as an acute primary appendicitis. Dieulafoy some years ago called attention to the fact that certain forms of appendicitis particularly were prone to infect the regions of the liver, resulting in general sepsis and death, or the formation of an abscess which for its ramifications seems to have no end. I have myself called attention several years ago to the fact that the postcecal and postcolonic cases were the ones in which we expected this manifestation of appendicitis. Ordinarily in the beginning of these cases the tenderness and the pain point is not the McBurney, but it is at the intersection of the angle 2 inches to the right of the umbilicus, and about 2 inches above the McBurney point. If in these cases this point of intersection is examined carefully, it will indicate the location of the appendix.

It is a fact that the delay in operating is most frequent in this class of cases, and the resulting consequences only emphasize what we already know, that it is a serious matter to delay diagnosis, and thus delay performance of appropriate and immediately demanded operation, which is necessary to avert these serious consequences.

In other words, this form of trouble frequently called empyema, after the abscess has perforated the diaphragm, and the patient is expectorating pus through the bronchial tubes, is still not an uncommon consequence and error at the present time; and it is because the profession does not make early diagnoses and still further because early operation is not done to prevent these ulterior sad consequences, that a reflection is cast on the diagnostic skill and acumen of the profession.

In reference to the abscess cases, my own rule has been to remove the appendix whenever possible, without opening the peritoneal cavity. I still see no urgent reason, in the absence of peritonitis and extravasation, why we should open the peritoneal cavity. Why not pursue the safer course and avoid the added danger of exposing to infection healthy peritoneum, and thus have occasional bad sequelæ in the form of general peritonitis and possible death.

With drainage, results are good; a second operation to remove the stump is seldom required, and when so, it is under more favorable conditions than exists in acute abscess.

Dr. Archibald MacLaren, St. Paul: The point which Dr. Knott raises here is the question of the treatment of peritonitis. We have all accepted Dr. Murphy's theory in regard to the treatment of general peritonitis, then by following Dr. Knott's suggestion we advance it to a protective measure and so we do away with the troublesome and dangerous complications which so often follow the older methods as we have all been accustomed to pursuing them.

The universal removal of the appendix, which was advocated by some surgeons a number of years ago, was on the wrong principle, because they did not provide for drainage of the cul-de-sac. The success of all acute appendiceal operations goes back to the proper drainage of the bottom of the peritoneal cavity. My own personal experience before adopting this suggestion of Dr. Knott's was that in 100 appendiceal abscess cases, I found that to get the patient well, I had to open and drain through the rectum fifteen times. Possibly some of these patients would have recovered if let alone—but when you have a distinct abscess pointing in the anterior wall of the rectum, the safe thing to do is to open and drain it. Now, by following Dr. Knott's suggestion in practically all these cases of appendicitis it has only been necessary to open the rectum twice in fifty cases. So that has reduced the necessity for rectal drainage in my experience just one-half.

One of these cases of rectal drainage is quite interesting, because the patient had originally come with an appendiceal abscess which had been opened above and drained. Six days later he had to have an opening through the rectum to get rid of an accumulation of pus. He recovered and was perfectly well for one year and a half. Then he came back again with another appendiceal abscess. This abscess was opened above and the appendix removed, a drain was put through a suprapubic stab into the cul-de-sac. He did well until the fourth day when he had to have his rectum opened again before he entirely recovered.

My experience during the last year agreed with Dr. Knott's. In all abscess cases, I have opened the abscess, broken down the adhesions and removed the appendix in every case without a death. I have had two deaths in appendiceal cases this past year. One was in a young man with acute general septic peritonitis, opened and drained in the first thirty hours. The other was an intestinal obstruction due to an adherent appendix, operated on after she had vomited fecal matter for over forty-eight hours. The first was a case we would all operate on under any system. The second should not have been operated on at all, but surgery had to shoulder the responsibility of neglect.

Dr. A. J. Ochsner, Chicago: The results in as skilled hands as Dr. Knott's I believe will be good with the removal of the appendix in practically all cases. I follow this rule: In any given case in which I can be practically certain that, with the experience that I have had with similar cases, the patient will get well if I remove the appendix, I always remove the appendix. If there is the least possible doubt in my mind concerning my ability in the case under consideration I drain and do not remove the appendix. I always drain in cases in which I do not remove the appendix. I leave the wound open entirely—put in an enormous drain and see to it that the patient gets a very handsome ventral hernia.

Then I direct this patient to live on liquids until the appendix is removed. In two instances in which I had not taken this precaution, the patients ate carelessly after a time and died, one of an acute intestinal obstruction and the other one of an acute recurrent gangrenous appendicitis with diffuse peritonitis. Both patients were shipped into the city from the northern peninsula of Michigan, and when they arrived they were practically dead. Since I had these two experiences in which I was not positive enough in my directions I insist on the patient living on liquids.

I have never lost one patient in these secondary cases since I have postponed the second operation until the acute conditions had entirely subsided, and I have never had one in which the ventral hernia could not be cured safely; but I do not hurry about the secondary operation. Some years ago I was anxious about these cases and sometimes made the secondary operation too early, and in that class of cases I lost several patients.

As regards opening down into the cul-de-sac, the results which the essayist gives show that this is a good method. But I have never followed this method, because by simply removing the appendix and making a stab wound laterally and draining through this stab wound and then placing the cecum down on the drainage and placing the omentum around the wound, my results have been satisfactory. But evidently this method is at least as satisfactory.

The point that Dr. Knott makes about placing the patient on the right side and keeping him there and keeping the head of the bed elevated is a very important matter. In our recovery wards we have three beds in a row, and I noticed some years ago that the patient who had the left side of his bed along the wall, and who was compelled therefore to lie on the right side, always did well; and the patient along the other wall never did well—because he could not be kept on his right side. He would roll over to see some other patient, speak to the nurse, or do something else equally reprehensible. Since that time I have insisted on placing this class of patients in the bed first mentioned.

Dr. William Fuller, Chicago: I believe the rule that should govern the surgeon in dealing with practically all acute suppurations, whether in the head, chest, abdominal or pelvic cavity, or elsewhere, is that of drainage and that only.

It is possible, of course, for skilled surgeons to remove the vermiform appendix in acute suppurative conditions, and instances may be met with in which the plan is a safe one; but when adhesions must be broken down in order to accomplish this step, it is not without danger in the best hands. For operators with moderate skill and for young surgeons the method is not to be recommended.

I heartily agree with Drs. Ochsner and Grant who do not, as a rule, break down adhesions to remove the appendix in acute cases; but who first drain, then remove the appendix later. Adhesions are life-savers and should not be disturbed merely for the purpose of removing an organ which can be removed without danger subsequently.

Dr. W. T. Reynolds, Kansas City, Mo.: Recent studies of the blood have taught us that in localized abscesses there has been an autogenous vaccination which has brought about a great resistance. In peritubal abscesses we never think of draining the abscess and leaving a leaky tube. The same proposition confronts us in the vast majority of instances in localized appendiceal abscesses. It is not usually hard to find a line of cleavage which makes it comparatively easy to divide the adhesions and find the diseased appendix. I am heartily in accord with the essayist and have found in my own experience a greatly reduced mortality in fearlessly draining from the bottom of the pelvis.

Dr. Van Buren Knott, Sioux City, Ia.: Not many years ago at a meeting of this society we listened to claims that no appendicitis patient should be operated on. So I am not surprised to find men still claiming that a leaking, stinking appendix should be left in an abdomen to make the patient as uncomfortable as possible. Reform does not always come at once, but slowly and usually through hard knocks. But as far as my own experience is concerned, I am removing this appendix for a different reason. Some seem to think that the removal of the appendix at the time of the original operation is merely a matter of cosmetics—not that there is any reason to think that its removal can do the patient any good. But that is not the point. We remove the appendix to lower the mortality; and my mortality has been reduced from 8 to 1 per cent. in these cases; and these men will have to show me a lower mortality than 1 per cent. in these abscess cases before I will agree with them.

Sioux City is a small town, but we are near Missouri; and we shall be glad to show anybody who doubts the kind of work we are doing there. Two or three good men in Omaha and in Kansas City, Dr. MacLaren, of St. Paul, and other men throughout the middle west, are doing this kind of work. Dr. Ross tells me he has not left an appendix in the abdomen in four years and that in nearly every one of these cases he has described to you of subphrenic abscess, that came to post-mortem, he found there was always an appendix left. It is a fact that patients will not die from peritonitis; we did not have a death from peritonitis in this series of cases. I believe most cases of circumscribed abscess will die of sepsis rather than peritonitis, and they will be more apt to die of sepsis if drainage is superficial.

I am surprised to find so many different hidden pus pockets scattered through the lower portion of the pelvic cavity. These could not be reached by incomplete surgery. In my experience such surgery leads to an unnecessarily high mortality.

It is all nonsense to say that after the abdomen is opened you will decide whether or not you will remove the appendix, because no man can decide whether an appendix will come out hard or easy, if it is more or less tangled with adhesions.

No one should undertake this operation who is going to occupy thirty minutes in finding the appendix and getting it out after the peritoneum is opened; and if he does start to remove it and backs out because it is a little hard, he has exposed his patient to all the trauma he would get any way.

Dr. Ochsner says if he thinks his patient is going to die, he leaves the appendix. But this is just the class of cases in which we remove them.

Dr. George G. Ross, Philadelphia: I agree with what Dr. Knott has said. I have not left an appendix in four years, and as yet I have had no occasion for regret.

I believe that the mortality in these acute appendicular localized abscesses is not so much due to the infection of the peritoneum as it is to the fact that the infection gets behind the endothelial coat of the peritoneum. It is this type of retroperitoneal infection that is attended by a very high mortality for the reason that the retroperitoneal space cannot be drained.

TUMORS OF THE MESENTERY

WITH A REPORT OF FOUR CASES *

HUBERT A. ROYSTER, A.B., M.D.
RALEIGH, N. C.

In spite of the contributions that have appeared from time to time concerning mesenteric tumors and the interest manifested in certain reported cases, there is good reason to believe that these growths have been neglected and that they have not received the systematic attention to which their importance entitles them. That they are comparatively uncommon is admitted; but this would seem to supply a stronger reason for their careful study. When one has to depend on text-books or even on readily available periodic literature, one must encounter serious difficulty in the management of such cases. Under the clearest conditions, they require judgment and, above all, experience which may be gained at the cost of stumbling on them unawares.

In this paper an attempt will be made, first, to classify the *existing pathologic and clinical knowledge of the* subject; second, to record some personal cases, which will bear on questions of diagnosis and operative method; and third, to review the important articles found in the recent literature. It will not be necessary to go into historic detail, since Douglas[1] covered the facts in 1903, and both Vance[2] and Bowers[3] restated them in 1906.

ORIGIN

Our topic includes only those tumors which originate in the mesentery itself and not the so-called retroperitoneal growths. The latter may arise from any tissue behind the peritoneum and push forward between the layers of the true mesentery. They have served in a way to confuse the classification.

In order to appreciate the situation and character of these tumors, it is well enough briefly to consider the mesentery, its development and its structure. Any fold of peritoneum connecting a part of the intestine to the posterior wall of the abdominal cavity may be called a mesentery, though this unqualified term is generally employed to designate the special portion of the membrane attached to the small intestine (*mesenterium commune*).

In the development of the embryo, as the right and the left halves of the body cavity come toward each other, the early connective tissue is compressed into a primitive mesentery, which is attached to the whole length of the alimentary tube, from the stomach to the anus. Intestine and peritoneum are developed together, two layers of the serous membrane investing the bowel. When fully formed the mesentery is fan-shaped, its length of insertion being many times that of its fixed attachment. It runs obliquely from left to right, extending from the second lumbar vertebra, crossing the spinal column, to the right sacro-iliac joint. Its root, or point of origin of the two layers, is 6 inches in length, while the convex intestinal edge is 21 feet long (Gray).

Between the two layers of peritoneum that constitute the mesentery, run arteries, veins, lymphatic vessels, lacteals, and nerves—all imbedded in connective tissue and fat. These enter and leave through the posterior space, where the intestine is not completely surrounded by serous membrane. It is readily seen, therefore, that tumors of the mesentery must be largely of the mesoblastic or connective tissue type.

VARIETIES

Growths of the mesentery may be solid or cystic. Cysts are by far the more common and, according to their contents, are either serous, chylous, hemorrhagic, hydatid or dermoid. Solid tumors are benign or malignant. The former are lipoma, myxoma and fibroma and the latter sarcoma. It is very probable that the lipomata greatly outnumber the others, but sarcomatous degeneration is said to take place sooner or later in the majority of the simpler neoplasms. The lipomata and fibromata are very often prone to attain an enormous size. The pathology of these tumors differs in nowise from that of similar growths in other organs.

ETIOLOGY

Little can be said of the etiology, because, indeed, little is known of it. Undoubtedly, some growths are congenital in origin, and certainly many exist for a long time before they are recognized. It is in such cases that the influence of trauma is given credence, for an injury may light up or call attention to a preexisting growth. Bachmann[4] refers to this fact in his report of the case of a boy of 9, who, eight weeks before examination, had fallen across a barrel and on whom an autopsy was done two months later, which showed large masses of multiple fibromata in the mesentery. He quotes Pean as having noted the fact that large tumors may be present for years, only to be revealed in their final stage by some sort of traumatism. Age and sex apparently are not factors in the occurrence of these growths. In childhood, however, we very rarely meet the solid tumors.

REPORT OF CASES

Before discussing more practical questions, it will be well to put on record the cases which form the basis of this paper. By virtue of those peculiar coincidences which sometimes crop out in our work, four mesenteric tumors fell to my lot last year, within the space of six months, the last three coming all within a period of a little more than one month. They are presented in the order of their occurrence.

CASE 1.—*Dermoid Cyst of the Sigmoid Mesocolon.*—Mrs. Y., aged about 40, of frail constitution, mother of three children, two weeks before coming under observation, had a sudden severe abdominal pain, beginning in the right iliac region, but quickly transferred to the left; she vomited and had fever. There was a history of previous colics and of one attack nearly a year before resembling this, except that the pain was chiefly in the bladder region.

Examination.—On the first visit, March 28, 1910, temperature was 101; there was pain and tenderness all over the abdomen, but particularly at the border of the left rectus, low down; very little distention. At the second visit, evening of same day, the tenderness was much less, but the fever much higher (104); local signs diminishing. It was agreed that no interference should be advised until the acute process had passed away. By April 12 there was a practical subsidence of fever and pain; the abdomen was flat and the patient's general condition was good. Local symptoms were centering in the right lower iliac region, where a very sensitive mass could be felt; this mass was easily palpated on bimanual examination and gave indistinct fluctuation. A likely diagnosis was pyosalpinx, but in the absence of any history leading to that affection, it was considered improbable. No definite statement was ventured.

Operation.—Rex Hospital, April 13, 1910: right rectus incision. A mass of adhesions was encountered around the bladder, uterus and cecum; the sigmoid flexure had been drawn far over to the right and within the folds of its mesentery, near the intestinal border, was found a somewhat flattened cyst of the size of an orange. In the process of enucleation the cyst was ruptured and the character of its contents—teeth, hair and bone embedded in a mushy material—was determined. The mesenteric vessels were uninjured and no ligatures were required, only whipping over the edges with catgut. The uterus, tubes and ovaries were normal; the appendix, being engaged in the adhesions, was removed. A drainage tube with tape was inserted into the lower angle of the wound.

The patient had a very pleasant recovery and is in better health than she had been for several years. The specimen (Fig. 1) is a typical dermoid cyst, containing hair and a well-marked alveolar process with several perfect teeth.

Dermoid cysts of the mesentery are, of course, very rare. According to Bell and Yeoman,[5] up to 1908 about 150 cases of mesenteric cysts were found scattered throughout the literature; but of all these cases, there are certainly not more than twenty described as dermoids. These writers report a dermoid of the jejunal mesentery in a woman of 24, which was felt as a large, round, tender and movable "lump" between the uterus and the bladder, and thought to be a fibromyoma of the uterus. It was found lying between the folds of the mesentery with a loop of bowel curving around it. Attempts at enucleation being unsuccessful, the entire cyst was excised, the hole in the mesentery closed and a loop of bowel resected. The patient made a tedious recovery. Ehler[6] also operated successfully on a patient, aged 22, for a dermoid cyst of the descending colon, which had to be dissected widely and was associated with another similar cyst at the hilum of the kidney. These two are the only other dermoids of the mesentery reported since 1907, and bring the number to not more than twenty-three, including the case herewith presented.

Dermoids, wherever found, have their origin in fetal inclusion or implantation from the ectoderm and are, therefore, congenital growths. They belong to the class of teratomata. The mesenteric forms are commonly derived as post-rectal dermoids, which may develop at any point along the infolding process. They do not usually give clinical signs until long after infantile life and are more apt to contain teeth than are dermoids in any other situation.

CASE 2.—*Sarcoma of Sigmoid Mesocolon.*—M. A. F., male, colored, aged 50, for several months had been troubled with abdominal pain and tenderness. At first his bladder was irritable; lately his rectum had been troubling him. He was sent in with a diagnosis of bladder tumor. He had lost about 30 pounds in weight.

Examination.—In appearance he was emaciated and hollow-eyed. The abdomen showed a hard nodular tumor, low down, near the mid-line, but chiefly to the left; on rectal examination it was found somewhat movable and apparently lying on the rectum. It had exactly the "feel" of a uterine fibroid in a woman.

Operation.—St. Agnes Hospital, Sept. 1, 1910: a low left rectus incision. About a pint of serous fluid was in the cavity. The large tumor (Fig. 2) was attached to the sigmoid flexure and was seen to spring from its mesentery. With some difficulty the growth was stripped off the bowel and enucleated from the mesosigmoid. The raw areas were closed with catgut. There were metastatic growths lower down, along the rectum and behind the bladder. The operation lasted twenty-five minutes.

At first the patient did well, but he became distended and vomited and, though his bowels moved and the pulse was never very rapid, he died on the fifth day. No autopsy was allowed. The pathologic report proved the tumor to be a round-cell sarcoma. It was not so soft as such growths usually are and was definitely encapsulated.

Since 1906, when Vance[2] reviewed the literature and in addition to his own case, found seven others of mesenteric sarcoma, there have been reported two more. These were both of mixed type. König's[7] case was that of a woman, 69 years of age, with cyanosis, dyspnea, anasarca, ascites and a feeble pulse. He tapped and drew off 15 liters of fluid, locating a tumor of the shape and size of a child's head below the umbilicus. Operation revealed a tumor, partly solid and partly cystic, growing from the mesentery and loop of small intestine. Extirpation and resection of portion of bowel, with use of the Murphy button. Uneventful recovery followed. Microscopic examination showed the tumor to be a fibrosarcoma with large spindle cells. Marullaz[8] presents the case of a man, aged 65, who had noticed swelling of the abdomen for two years. It was 108 cm. in circumference; the patient's general condition was poor, but no edema or ascites was present. At operation the large growth was found adherent to the stomach and transverse colon; resection was necessary for its removal and the patient died thirty-six hours afterward. The tumor weighed over 6 kg., and turned out to be a myxosarcoma of the mesentery.

Case 3.—*Blood Tumor of Mesentery.*—J. S. F., male, aged 60, had always been healthy up to a year ago, when he began to have pain in his right side. He was treated in January, 1910, for what was thought to be appendicitis. He seemed to recover in four days and did not complain again for six months. At that time an enlargement was found in his right abdomen. He was then advised to seek surgical aid, but declined. For the past three months he had lost much flesh and strength, but had been almost free from acute pain.

Examination.—There was found in the right half of the abdomen a swelling of the size of a grapefruit, located almost on a level with the umbilicus. It was freely movable and seemed too far forward for the kidney. A mesenteric growth was the most probable condition.

Operation.—At Rex Hospital, Sept. 23, 1910: an incision in the right rectus muscle exposed the hard nodular dark-red tumor, which grew in the mesentery of the ileum. It encroached so closely on the intestinal wall and appeared so plainly malignant that a lateral anastomosis was decided on. Nine inches of the bowel were removed along with a corresponding amount of mesentery down to its root. The patient did very well until the second day, when he suddenly developed pain, vomiting and delirium without unusual distention, and died probably from gangrene of the intestine. It was impossible to make a post-mortem examination. The pathologist's report, somewhat of a surprise, was as follows: "Sections from four different portions of tumor show only young connective tissue (an organizing clot). No indication of malignancy" (Fig. 3).

This was a very difficult case. Resection was undoubtedly demanded, and yet one hardly hoped to have success with it. The large V-shaped portion of mesentery, which had to be excised, contained thrombosed blood-vessels, and they probably extended into apparently healthy areas beyond the line of division. Malignant degeneration of a preexisting growth was certainly suggested by the history. Possibly a slow-forming mesenteric thrombosis may have accounted for the condition. There is a chronic thrombosis which gives rise to a large blood tumor between the layers of the mesentery, but it is much more rare than the acute form. Codman,[9] in speaking of this condition, says: "I have not made the diagnosis in any of them, nor do I expect to in the next." According to Douglas,[1] mesenteric blood-cysts may be due to injury with non-absorption of the effusion or to hemorrhage into a preformed cyst, as observed by himself. No sort of possible history of traumatism could be elicited in the case now being considered. So, in the light of the pathologic findings, it has been put down as a blood-tumor of the mesentery, due most probably to a long-continued process of embolism and thrombosis.

Case 4.—*Round-Cell Sarcoma of Transverse Mesocolon.*—Mrs. G. W. D., 52 years old, had her menopause in 1904. In June, 1910, she began to flow again and this went on almost continually to the time of her admission on Oct. 6, 1910. Soon after the flow started, she felt an enlargement in her right side, accompanied by more or less pain. This lump continued to grow rapidly. During this time she lost weight, perhaps 20 pounds or more, and did not feel well at any time.

Examination.—A very freely movable tumor, about 8 inches long and 4 inches wide, soft in consistency, was found apparently attached near median line, below and just to the right of the umbilicus; it could be pushed into the pelvic region and might easily be mistaken for an ovarian cyst; the uterus was normal; no growth on the cervix or on the endometrium; the adnexa showed no disease.

Operation.—Oct. 7, 1910, Rex Hospital: A long median incision below the umbilicus revealed a mass rolled up in the omentum. This was tied off and the tumor brought up. It was a growth (evidently sarcoma) of the transverse mesocolon, and was shelled out without wounding the bowel or the mesenteric vessels. The bleeding was easily controlled. Hard metastatic nodules were felt in the pelvic cul-de-sac. The pathologist reported "sarcoma—round-cell type."

The patient made an easy operative recovery and went home in two weeks. Before she left the hospital, the growth was larger than it was when she came in, and she died at her home about one month later.

There was no opportunity here to do any bowel resection owing to the secondary growths and the patient's enfeebled condition. The diagnosis was evident from the rapidity of the tumor growth and the patient's malignant appearance. It was a typical mesenteric sarcoma (Fig. 4), its consistency being, as described by Bazin,[10] "neither soft nor fluctuating, but pasty; the surface not smooth but lobulated." It differed markedly from that of the second case in this series, though they were of the same cellular type. The comments made under that case will apply here.

DIAGNOSIS

One hesitates to lay down any rules whatever for the diagnosis of mesenteric tumors. It is often impossible to say beforehand that a recognizable enlargement is certainly a growth of the mesentery, and it may be well to feel contented simply with deciding in most cases that surgical intervention is or is not indicated. Exploratory diagnosis is unquestionably the easiest and surest way. A few principles for guidance, however, may be set forth, these being based on the collected experience of those who have in late years written on the subject. Douglas is the only author who gives adequate consideration to the diagnosis. I shall not here undertake a labored presentation of symptoms and signs. Rather will it be better profit to lay emphasis on those things which point to an existing tumor as being possibly mesenteric and to mention those conditions which might prevent confusion in distinguishing this growth from some other neoplasm.

Subjective symptoms, if present, are not usually distinctive. Pain, which is the most important, is not apt to be attributed to the rare condition of a mesenteric tumor, but more probably to biliary, nephritic or appendicular colic; constipation is nearly always the rule, and digestive troubles, especially nausea and vomiting, are common, but so they are in many other conditions. Intestinal occlusion, volvulus and invagination may result from the presence of the tumor and give the symptoms attending those conditions.

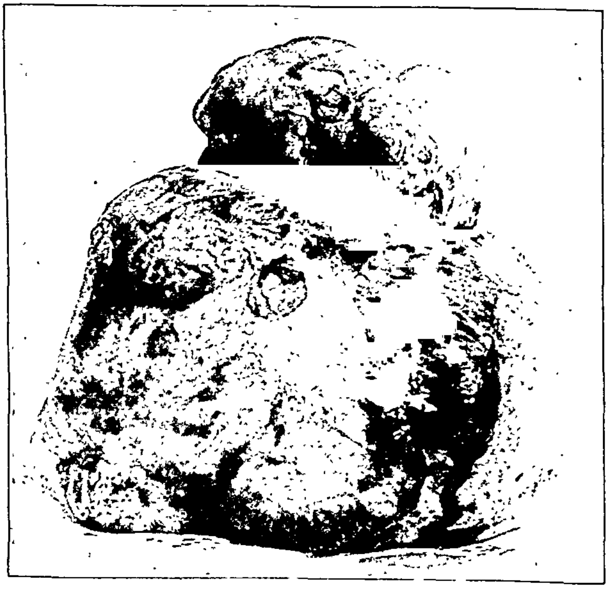

Fig. 2.—Sarcoma of sigmoid mesocolon.

The signs that most clearly give evidence of mesenteric tumors concern their position, their mobility and their relation to other organs. They are situated either in the middle line or far to either side over the course of the large bowel. Free mobility is the most important single sign, as no other abdominal tumor will show this to the same degree. The motion from side to side is especially marked. This may in a measure be diminished when the tumor is allowed to advance to a great size. If it can be determined that the tumor is separable from the solid viscera, a long step forward in the diagnosis will be made. Bazin speaks of a zone of resonance in front of or below the growth, and Douglas suggests that this may be of value in eliminating pelvic tumors, if the patient is examined in the Trendelenburg posture. König regards these as the important points: colicky pains radiating toward the umbilicus, the presence of bowel over the tumor and unusual mobility of the growth; and yet in his case none of these signs was present. Ascites is one of the common complications.

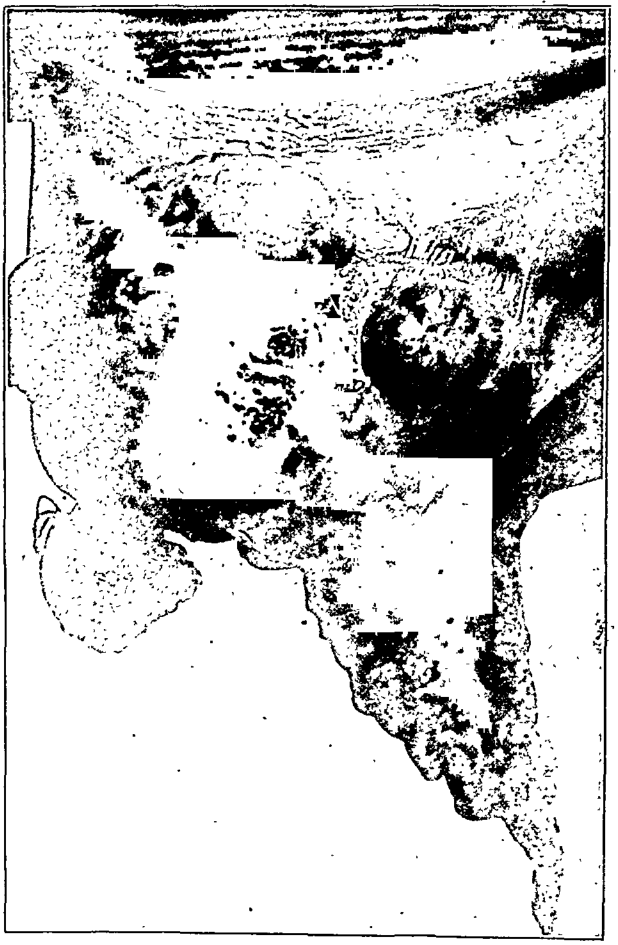

Fig. 3.—Blood tumor of mesentery.

The differential diagnosis offers a wide field of problems. Chief among these are ovarian cysts (which figured very strongly in the fourth case of my series), tumors of the liver, enlargements or displacements of the kidney, growths of the bowel itself and cysts of the pancreas. It will hardly be expedient to go over the detailed characteristics of these conditions, as they are well known. One must keep them strongly in mind, however, when differentiating abdominal growths and be prepared to learn that the diagnosis of mesenteric tumors is not a simple affair. Their very rarity is a reason for their being often overlooked. Reporting a fibromyxolipoma of the mesentery four years ago, Wiesinger[11] remarked: "In the many thousand laparotomies performed by the author for several years, this is the only case he has observed." Cysts, more than the solid tumors, are likely to furnish sources of error in diagnosis, from the areas of fluctuation usually present. These may be noted also in a lipoma when soft and of large size, as mentioned by Terrier. Bazin considers the diagnosis of sarcoma very difficult. He lays stress on "the rapidity of the growth, the cachexia and the more or less profound yellow tint of cancer." Furthermore, he seems to advise aspiratory puncture; this, he states, "will yield a cystic liquid mixed with blood, which is not the case in a lipoma owing to its lack of vascular supply." The European surgeons, as a rule, write very unconcernedly of this method, as if it were their custom to aspirate all abdominal swellings for diagnostic purposes—a practice which surely cannot be commended. Myxoma of the mesentery has been confounded with multilocular cyst of the ovary. Diagnosis must depend on excluding all possible evidence of the latter.

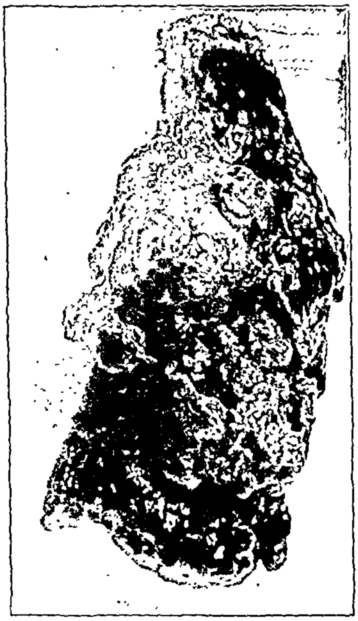

Fig. 4.—Round-cell sarcoma of transverse mesocolon.

PROGNOSIS

The outlook depends largely on the character of the growth. Danger results not only from malignancy which may be present or imminent, but also from pressure due to the large size such tumors often attain. Early recognition and prompt removal are the remedies for both of these perils. Unfortunately, late diagnosis and tardy removal have appeared to be the order of the day, and thus the mortality has been high. In 1898 Begouin collected notes of twenty-nine solid tumors of the mesentery; of the patients only fourteen survived the operation (mortality 51.7 per cent.). Writers have since stated that our results are now better; but more recent reports do not show great improvement. Vance, in 1906, found twenty-seven cases in the literature of the five years preceding and eleven of the patients died, a mortality of 40.7 per cent. Since that date, I have records of nine cases (including two dermoids) with three deaths; these, added to the four of my own, give a total of thirteen cases with six deaths, or 45.1 per cent. mortality.

OPERATIVE METHODS

In deciding on the proper procedure at the operation, one must have in mind three questions: First, is the tumor benign or malignant? Second, is it primary and isolated? Third, how much, if any, intestine is to be sacrificed in its extirpation? These points are often very difficult to determine. Since the last issue must depend on the first two, the whole matter may be resolved into a decision on the indications in any given case for resection of the bowel. The mortality percentage will be closely concerned with this decision. In Vance's twenty-seven collected operations the intestine was resected thirteen times, with seven recoveries and six deaths; three of the tumors were sarcomata and all the patients died, while of the five fibromata cases only one resulted fatally. Obviously, one should be aware of the risk when electing to perform resection. Yet Murphy removed two feet of bowel, Lexer six and a half feet, and Shepherd seven feet eight inches, all successfully, for benign growths. It must be conceded, of course, that the cases suitable for resection are those in which malignancy is evident or in which the growth by its size or situation encroaches dangerously on the bowel: both of these conditions will naturally be associated with a high death-rate. Most assuredly the danger is increased by the removal of a portion of the bowel and the time consumed in the consequent anastomosis, on account either of shock, which has been given as the cause of death in many of the operations, or of gangrene of the intestine, resulting from injury to the nutrient vessels, or of peritonitis, due to imperfect technic. We can heartily join Wiesinger, therefore, in his advice to avoid resection wherever possible, and, as a sort of corollary, to be careful not to wound the blood-vessels of the mesentery in extirpating the tumor. When that golden age shall arrive, in which the surgeon will be given early the privilege of examining and, if it seem wise, of operating on these patients promptly, then the vexatious questions which have just claimed our attention may trouble us less and less.

HAVE WE AN IDEAL OPERATION FOR INTERNAL HEMORRHOIDS?

A NEW HEMORRHOID CLAMP

A. B. COOKE, M.D.
NASHVILLE, TENN.

It is proper to acknowledge, by way of introduction, that no operation in surgery of equal importance has been performed as often or with as uniform success as that for the relief of internal hemorrhoids. This record is all the more remarkable when the number and indiscriminate qualifications of the operators are considered, and when the many diverse methods advocated and practiced are called to mind.

It is probably no exaggeration to say that operation by the ligature and clamp-and-cautery methods has been performed hundreds of thousands of times under every imaginable condition, with a resulting mortality so low as to be practically negligible. And the same is true of an additional large number of cases in which the long list of modified and new methods have been employed. With this phenomenal history of achievement, it would seem that there is little ground for criticism either of the standard or of the more recently devised methods of operating. And let me hasten to add that such is not the purpose of the present brief paper, except in so far as the several methods fail to conform to the accepted principles and precepts of modern surgery.

Now what are those principles and precepts as applied to the surgery of internal hemorrhoids? Among the more important are: (1) complete hemostasis, (2) immediate closure of the operative wounds, (3) preservation of the function of the parts, (4) permanency of cure, and (5) due consideration of the factors of safety, simplicity of technic, time required for recovery, and the amount of post-operative pain. Antisepsis is not included in the list for the reason that at the present time this is recognized as the indispensable requisite of all surgery.

Considering first the two older or, as they may be properly termed, standard, methods of operating, in the light of the requirements enumerated, we find that each is open to criticism on one or more counts.

The ligature operation conforms to all the principles laid down except the second; that the open wounds with the sloughing stumps and granulating surfaces resulting when this method is employed are far from ideal, cannot be gainsaid; indeed, it is one of the wonders of rectal surgery that infection and disaster do not follow this operation uniformly instead of so rarely as to be virtually unknown. In this one important respect the operation by ligature is to be strongly condemned.

The clamp-and-cautery operation meets perfectly the first four requirements, but fails to meet the fifth. As performed by the average operator it is neither so safe and simple nor so expeditious and painless as to merit unqualified endorsement. Secondary hemorrhage following this method is by no means unknown; the technic is far from simple, an elaborate apparatus and an extra assistant being always required; the operation itself consumes more time and the period of confinement is certainly not shortened; and finally the amount of post-operative pain is greater than follows any other method in common practice. It cannot be said, therefore, that the method is beyond criticism, even though the final results approach the ideal.

Of the numerous more recently devised methods, I shall only refer to the three which are probably best known and most distinctive in conception. Of the five classes of principles laid down by which to estimate the merits of the various operative procedures, the Whitehead operation conforms to only two; i. e., the second and fourth. The vitally important principles embodied in the third and fifth classes are totally disregarded, while that of the first class is practically ignored during the progress of the work itself. The enormous loss of blood incident to the performance of the Whitehead operation is a serious drawback. Scarcely less so is the ever-present danger of impairment of the function of the part by the substitution of abnormal relations or as the result of vicious cicatrization. It is also the most dangerous as well as the most complicated of all operations for internal hemorrhoids. Added to this series of disadvantages is the further consideration, which I state as a personal conviction, that it is both an unnecessary and an unjustifiable procedure. Of the many hundreds of patients operated on by me, I do not now recall a single one in whom the Whitehead technic seemed especially indicated, and I have never had occasion to regret the choice of another method.

The operation by means of Earl's clamp is in reality a modification of the Whitehead method. It is also a distinct improvement on it, in that the great loss of blood is prevented and the important advantages of comparative safety and simplicity gained. But it is open to the same indictment under class 3; namely, that it presents the practically identical danger of interference with the function of the parts.

Pennington's enucleation operation is an ingenious one, and one which has many features to commend it; but it unquestionably falls short with reference to the first-named of our arbitrary list of surgical principles. In the skilful hands of its experienced originator, the danger of hemorrhage may be and doubtless is reduced to a minimum, but in the hands of the average operator this feature of inadequate hemostasis certainly constitutes a glaring and formidable objection. It is, moreover, by no means a simple procedure either in the execution of the operative work or in the care and discrimination required in the adjustment of a proper dressing.

Now, after the foregoing iconoclastic onslaught, the question will at once be asked, does the critic know of a method more free from objections? With all becoming humility I answer, he believes he does.

The clamp and suture operation performed according to the following technic fullfils perfectly all of the conditions embodied under the five headings: A narrow clamp with tapering blades is applied to the base of the hemorrhoid to be removed in a direction parallel with the long axis of the intestine and so that its smaller, or free, extremity engages the upper, or proximal, portion of the tumor. By depressing the handle of the clamp the end of the blades where the suturing is to begin is brought into full view. A No. 1 or No. 2 chromicized cat-gut suture threaded on a round, half-curved needle is now passed beneath the tip of the clamp and securely tied on the sound mucosa above the base of the tumor. This is the most important step of the operation as, if properly executed, the blood-supply of the tumor that is being dealt with is at once effectively controlled. With scalpel or scissors the portion of the tumor outside the grasp of the clamp is amputated and a continuous suture inserted over the clamp blades, as in the Earl operation. The clamp is then gently loosened and withdrawn and the suture carefully and uniformly tightened and secured at the skin margin. Each pile tumor in turn is treated in a similar manner. If one or more of the growths is of the externo-internal variety, the clamp should be so adjusted as to include as much of the anal margin as may be indicated at each application. In order to avoid the possibility of the tissues slipping from the grasp of the clamp, it is best to amputate the overlying portion of the tumor by degrees, following the knife or scissors closely with the sutures. As a rule the sutures should be placed from 1/6 to 1/8 of an inch apart, though when the first one is properly placed, the danger of hemorrhage is largely eliminated and approximation of the edges of the mucosa is the chief purpose of the remainder.

The only dressing required is a small, well-lubricated, strip of gauze passed into the rectum, an external compress and pad and a T-badge. The operation can be performed very rapidly with a little experience, the amount of time required in a given case depending, of course, to a great extent on the number of tumors to be removed. The post-operative pain is not greater either in degree or duration than that following other methods and convalescence is fully as rapid.

This method lends itself to local as well as general anesthesia, though in the former case rapidity of operation is much more essential, particularly if multiple tumors are to be removed. Special attention to antisepsis is necessary in order to obtain the best results.

It will be observed that this method is closely analogous to the clamp-and-cautery operation, the only difference in technic being that in the former the suture instead of the cautery is relied on for hemostasis and permanent closure of the wound. That, when properly applied, it is much more dependable for these purposes cannot be denied. In addition, in my experience, it is followed by less after-pain and fewer reflex disturbances.

Considered in the abstract, I have always regarded the clamp-and-cautery method as more perfectly meeting the surgical conditions involved in the operative treatment of internal hemorrhoids than any other in general use. If, as I believe is true, the method here presented retains the advantages of the former at the same time that it overcomes in a practical way its few defects, I am prepared to say that it is the most nearly ideal of all methods yet devised.

I would have it distinctly understood that I claim neither priority nor originality for the technic here advocated. It has probably been described before, but I have not sought to ascertain by whom first, or when. My object has been rather to emphasize its value and again bring it to the attention of the workers in this field. Many times in recent years, particularly when performing operations on adjacent organs at the same time, e. g., lacerated perineum, I have resorted to it because of its obvious advantages. More lately I have been employing it frequently in simple cases, and always with complete satisfaction.

The only new feature I wish to call attention to is the clamp herewith presented, which, as will be at once recognized, is merely a modification, or rather an adaptation, of the original pattern of Earl's clamp. Formerly I used merely a pair of narrow-bladed artery forceps and, while they answered the purpose fairly well, I always recognized the need of a longer and stronger clamp of similar design. I have had occasion to use the new instrument only a few times as yet, but can unreservedly recommend it to those who may be sufficiently impressed to give the method a trial.

EXPERIMENTAL DIRECT TRANSPLANTATION OF TENDON AND FASCIA *

DEAN LEWIS, M.D., and CARL B. DAVIS, M.D.
CHICAGO

Tendon and fascia are not highly differentiated, regenerate rapidly, under favorable conditions, to repair extensive defects and require but little blood to maintain functional activity. They should, therefore, be well suited for purposes of direct transplantation. The feasibility of the direct transplantation of tendon and fascia first suggested itself to us some two years ago while repairing an extensive defect of the extensor tendons of the fingers resulting from a burn by a hot rolling iron such as is commonly used in steam laundries. The space to be bridged was so wide that it was necessary that the long tendinous flaps, which had to be used, should remain attached to the parent tendon by merely enough tissue to insure continuity. Although in this case the greater part of the tendinous flaps were independent of the parent tendon so far as nutrition is concerned, the functional result, complete extension of the fingers together and independently, was perfect.

Gluck,[1] while experimenting on the direct transplantation of muscle, was the first to demonstrate that tendons could be transplanted directly. He transplanted the gastrocnemius from one fowl to another and demonstrated that the function of the transplanted segment could be maintained. The tendo Achillis, which had been transplanted with the muscle in these experiments, had a perfectly normal gross appearance when examined. One of the transplanted tendons was examined after forty days. No histologic examination of the transplanted segments was made; at least, no mention is made of such an examination.

This experimental work never had a very extensive practical application, but few cases having been reported in which direct tendon transplantation has been attempted in man. Heuck,[2] in 1893, while repairing a defect in the long extensor of the thumb, accidentally tore off the flap from the parent tendon. The completely separated flap was sutured in position, and, notwithstanding that two pieces of the transplanted tendon sloughed out, a good result was finally obtained.

Peyrot,[3] in 1887, used a heteroplastic transplant with apparent success. In this case both flexor tendons of the left middle finger had been lost. A piece of tendon 4 cm. in length was removed from a young dog and sutured into the defect with catgut sutures. The transplant healed in position, although the cutaneous wound did not heal by primary intention. In this case the function was not completely restored, but it was greatly improved.

Monod,[4] the same year, transplanted a tendon from the hind leg of a rabbit into a defect in the flexor longus pollicis measuring 5 cm. in length. The functional result of this operation is reported as perfect, a thick, round tendon being felt at the site where the transplant was inserted. Monod was unable to state whether the transplanted segment acted as a bridge or as a true substitute for that which had been lost. Mainzer,[5] in 1902, reports two cases in which direct homotransplants were used successfully to bridge over defects while transferring tendons. In his first case, the tendon of the paralyzed peroneus tertius was used as a direct transplant to bridge a space between a flap taken from the tendo Achillis and the extensor longus digitorum. In this case the patient could extend the toes and flex the foot after thirteen weeks and could walk normally after one year. In the second case the tendon of the peroneus tertius was used as a direct transplant to unite a flap from the tendo Achillis with the extensor longus digitorum. Dorsal flexion of the foot was good after seven days. These are about the only instances in which direct transplantation of tendon has been attempted in man.

Plastic operations on tendons by means of dead foreign material such as catgut, silver wire and silk have never been used extensively in the repair of defects of the flexor and extensor tendons of the fingers, notwithstanding that the silk tendon, as employed by Lange, has yielded such brilliant results in the correction of palsies following infantile paralysis. Lange himself says,

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

concerning the repair of tendon defects caused by suppuration, that the infection remaining at the site where the artificial tendon is to be inserted may cause the latter to be extruded, and that even if the artificial tendon healed in position, the dense scar tissue may lead to such strong adhesions that the function of the artificial tendon may be seriously interfered with. It is in the repair of defects of the flexor and extensor tendons that a living transplant is especially desirable, although the autoplastic operation devised by von Hacker[6] some eight years ago has given results in his hands which can hardly be improved on.

Dogs were used in the experimental work which has been done by us. In one series of experiments, pieces of tendon measuring 1 or 1¼ inches were removed from the tendo Achillis of one dog and inserted into a defect of about the same length in the tendo Achillis of another dog. The legs of these animals were immobilized long enough to insure integrity of the sutures, then the cast was removed, for as will be shown later, early use of the leg in which the transplant is inserted seems to have an important effect on the viability and development of the transplant.

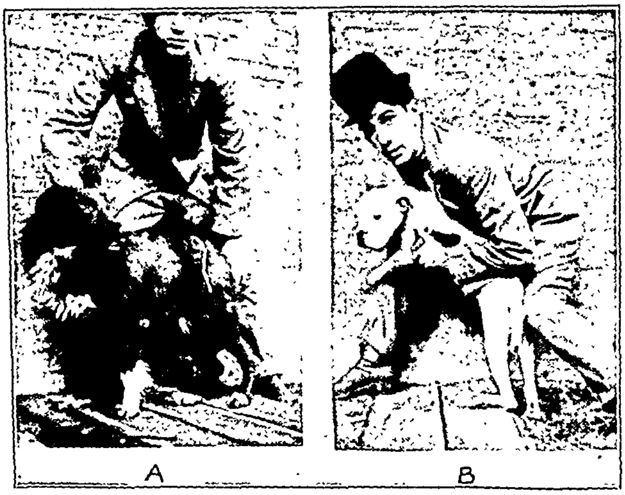

Fig. 1.—A dog from left hind leg of which a piece of tendon one and one-quarter inches in length had been removed and replaced by a piece of tendon of about the same length from another one. Picture taken four weeks after transplantation. The dog walked in two weeks after the operation, with only a slight limp. B, control dog. A piece of tendon measuring from one to one and one-quarter inches was removed and not replaced. The heel drops, resting on the board.

In another series of experiments pieces of tendon measuring 1 or 1¼ inches were removed from the tendo Achillis and inserted into a pocket in the subcutaneous fat of the abdomen. These pieces were placed in the subcutaneous fat rather than in the muscle or between the fascia, because the circulation would not be so readily established. The experiment was thus subjected to a severe test and, besides, if direct transplantation were attempted, it would be advisable to run the transplant through tunnels in the subcutaneous fat whenever possible.

In studying the fate of fascial transplants, strips of fascia lata or of the sheath of the rectus abdominis measuring ¾ inch in length and ½ inch in width were dissected loose and buried either under the subcutaneous fat or placed free on the fascial plate from which they had been separated.

TENDON EXCHANGE, THE TENDO ACHILLIS BEING TRANSFERRED FROM ONE DOG TO ANOTHER WITH EARLY USE OF THE LEG AFTER THE OPERATION

The tendon transfers were made under careful aseptic precautions, as primary wound healing is essential to success. The pieces of tendon were traumatized as little as possible and protected from drying during the process of transplantation. In order to insure early use of the leg, without danger of separating the transplant from the muscle and tendon to which it had been sutured, rather heavy iodin catgut or Pagenstecher's linen were used and accurate approximation of the ends secured. It is important that the leg carrying the transplant be used early. Some dogs, in which a piece of tendon had been removed and not replaced, were used as controls. These animals always walked with a drop foot, there being no restoration of function. In one control dog, the defect remaining after removal of the tendon was filled in by new tissue. This differed markedly, however, from the transplant, and although there was in this case what might be called an anatomical restoration of the tendon, there was no return of function. This tissue was present forty-five days after the segment had been removed.

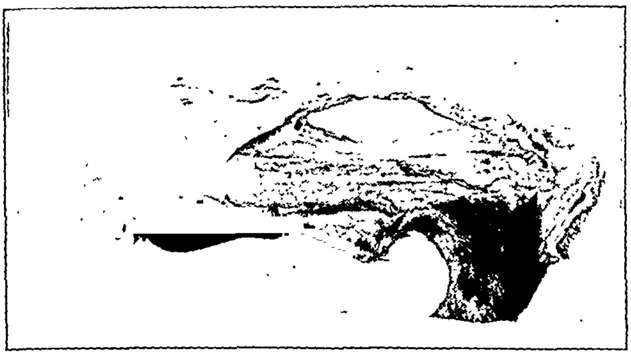

Fig. 2.—Appearance of tendon three weeks after transplantation. The transplanted tendon is larger than the normal one on the opposite side. It is fusiform in shape and does not taper down to its insertion as the normal tendon does. The line of suture can no longer be made out.

The transplanted tendons were examined after seven, seventeen, twenty-one, thirty-five and fifty-nine days. In these cases a round, resistant, somewhat enlarged tendon could be felt beneath the skin under which it moved quite freely. In some of our cases, the transplant underwent regressive changes as the result of infection or of undue tension on the segment. In these the transplant became soft and pulpified and imparted to the palpating finger a much different sensation than that imparted by the living transplant. In all of the successful cases, the dog could use the leg at the end of a week, and at the end of fourteen or fifteen days, the animal could walk without much of a limp or any dropping of the foot.

We will not give a minute description of the changes occurring in each case, but will mention those which we consider to be most characteristic.

Some of the most important changes relate to the size and form of the transplant. At the end of seven days the transplanted segment, which has not increased much in size, lies in a mantle of grayish red embryonal tissue which is usually separated from the transplant proper by a thin layer of plasma. At the end of seventeen days the transplant shows some enlargement, and the mantle of granulation tissue which surrounds it has formed a rather intimate union with the transplanted tissue. At the end of three weeks, the tendon transplant is from two to three times thicker than the normal tendon on the opposite side. In the tendo Achillis of the dog there are three separate tendon bundles, each surrounded by a synovial sheath. In the transplanted tendon these three bundles become united so that they can no longer be isolated, this union being due apparently to proliferative changes in the peritendineum.

[6] Von Hacker: Ueber den autoplastischen Ersatz der Streck und der Beugesehnen durch entbehrliche Sehnen des Handrückens, Beitr. z. klin. Chir., 1910, lxvi, 259.

This change in size has been noted by both Kirschner[7] and Rehn[8] in their experimental work dealing with transplantations of tendon. In describing a tendon examined thirty-three days after transplantation, Kirschner remarks that the exposed tendon appears as a rounded cord which is about twice as thick as the normal tendon on the opposite side, and that it is so sharply delimited from the surrounding tissues that there is no doubt as to the exact limits of the transplanted tendon. Rehn says, in describing one of his specimens removed after seven weeks, that the transplanted segment is about three times as thick as the tendon on the opposite side.

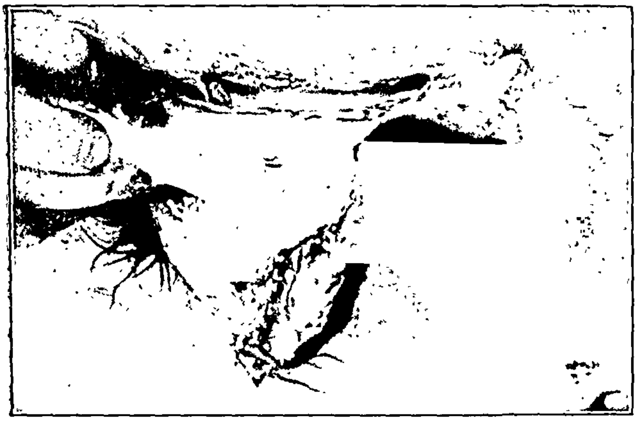

Fig. 3.—Appearance of tendon fifty-nine days after transplantation. The tendon resembles quite closely a normal one. It is still somewhat larger than the normal one on the opposite side, but it approaches the normal closely in shape, tapering down to its point of attachment, being no longer fusiform.

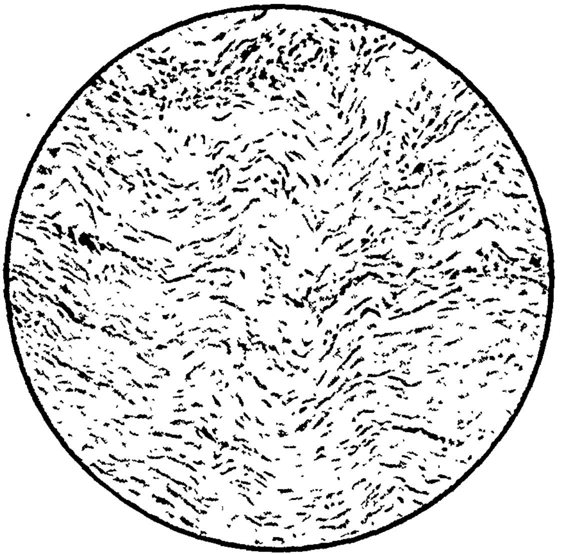

Fig. 4.—Longitudinal section through a tendon three weeks after transplantation. The fibrillæ and nuclei stain well and appear practically normal. There are some proliferative changes in the peritendineum.

The tendon transplants become fusiform in shape and do not taper down to their point of attachment as does the normal tendo Achillis. The center of the transplant is usually the widest part, there being a gradual reduction in size on either side of the middle of the transplant down to the suture line.

The changes in size and shape of the transplants are due, we believe, to two things: (1) proliferative changes in the subcutaneous tissue surrounding the transplanted tendon and in the peritendineum externum and internum; (2) edema of the transplant, resulting from an imperfect reestablishment of the circulation.

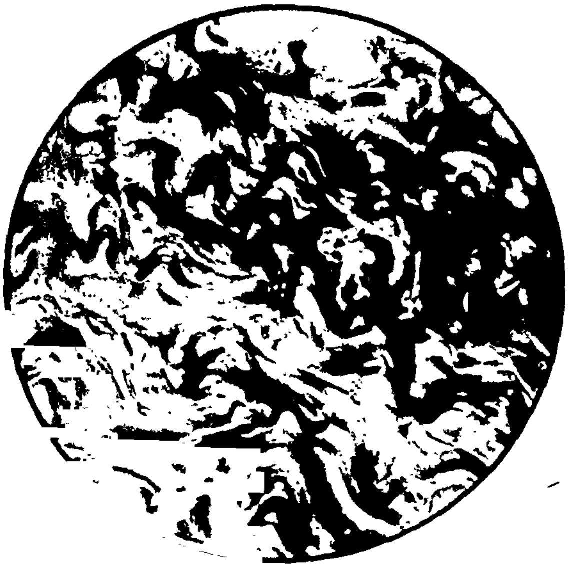

Fig. 5.—Section parallel to long axis of tendon five weeks after transplantation, showing swollen curled fibers of transplant.

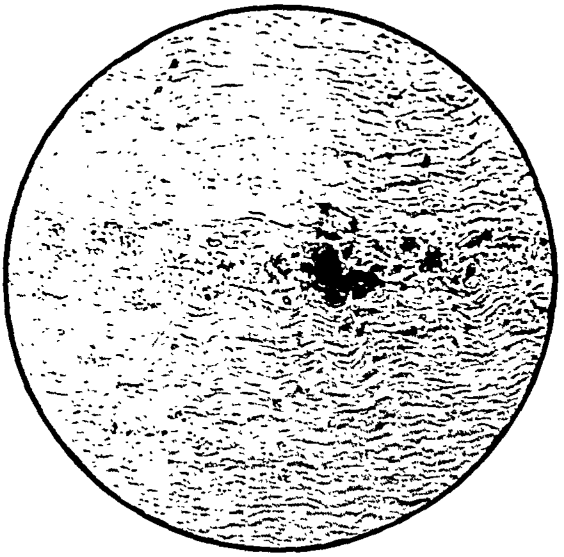

Fig. 6.—Longitudinal section through tendon fifty-nine days after transplantation. Tendon practically normal.

As regards the proliferative changes in the peritendineum externum and internum, our findings are in accord with those of Rehn. He states that, during the first three weeks after transplantation, proliferative changes in the peritendineum are the most prominent of

[8] Rehn, E.: Die homoplastische Sehnentransplantation im Tierexperiment, Beitr. z. klin. Chir., 1910, lxviii, 417.

any occurring in the transplanted tendon, and that by the twenty-first day the peritendineum externum has proliferated to form a thick mantle of newly formed tendon tissue which surrounds the transplanted segment and supplies the latter by numerous capillaries which develop from it with nutrition.

The mantle of tissue which we have observed is developed partly from the peritendineum externum and partly from the subcutaneous tissues which form the bed for the transplanted segment. This mantle of tissue is rich in blood-supply, and undoubtedly furnishes the greater part of the nutrition for the transplanted tendon. When the proliferative changes in the transplant are most marked, the mantle of proliferating tissue and the transplanted segment are closely united.

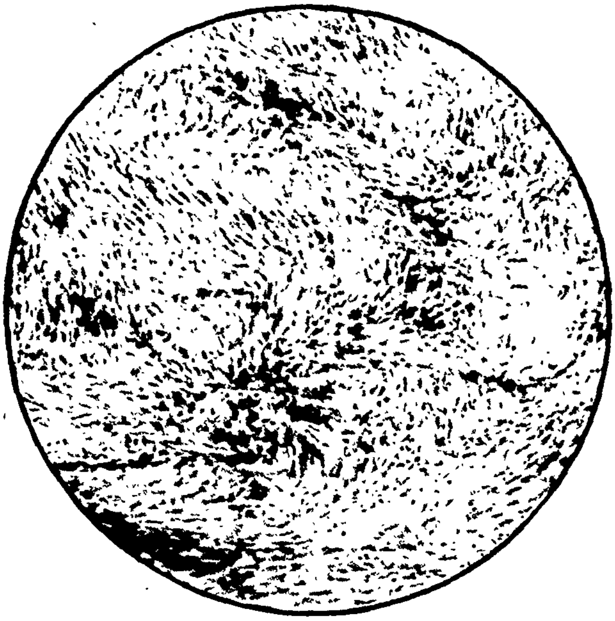

Fig. 7.—Cross-section through piece of tendon transplanted into the subcutaneous fat and removed after five weeks. Piece of tendon reduced considerably in size. There is considerable leukocytic infiltration in certain areas. Neither the fibrillæ nor the peritendineum show an evidence of proliferative changes.

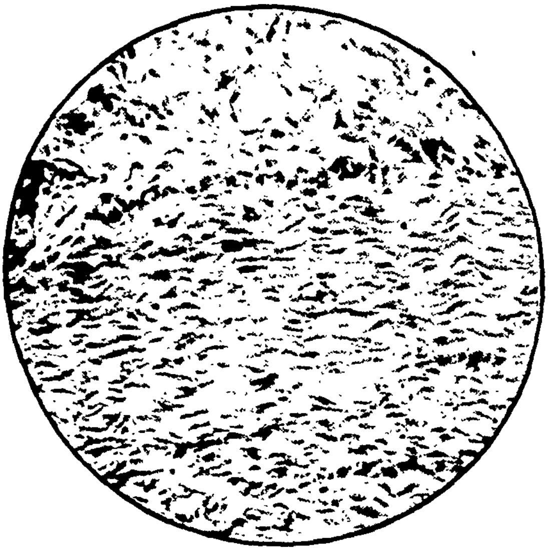

Fig. 8.—Fascial transplant removed after fourteen days. The transplanted tissue preserves all of the characteristics of normal fascia.

CHANGES IN SIZE OF THE FIBRILLÆ AND EDEMA OF THE TRANSPLANT

In the transplanted tendons, after three and five weeks, the fibrillæ seem to be larger than normal, and many seem to be gnarled and twisted, the bundles of fibrillæ often being separated by a granular mass. Although these changes are most marked in the three and five weeks old transplants, they are also observed as late as fifty-nine days after the tendons have been exchanged.

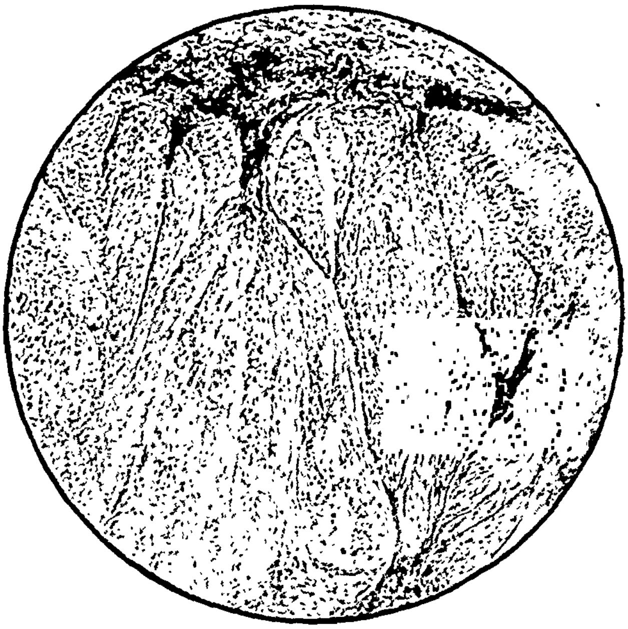

Fig. 9.—Cross-section of a piece of fascia from the rectus abdominis transplanted into the subcutaneous fat of the abdomen and removed twenty-three days later.

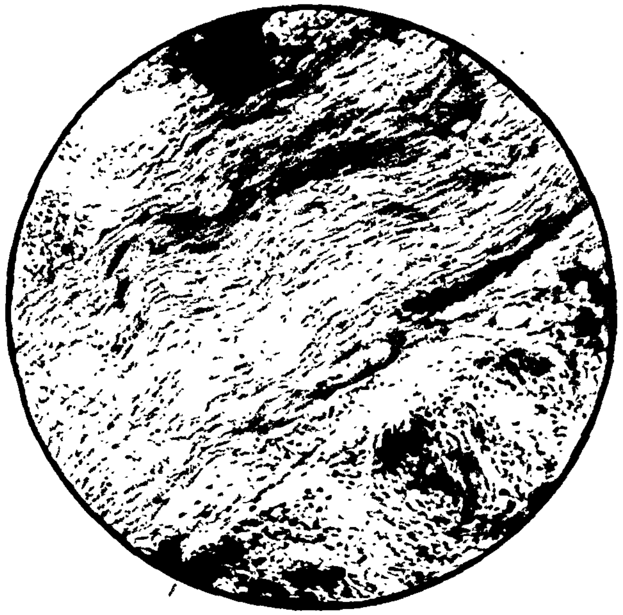

Fig. 10.—Longitudinal section of a piece of fascia removed from the rectus abdominis and transplanted into a subcutaneous pocket in the abdominal wall. Fascia examined thirty-five days after transplantation.

These changes we believe to be due to an edema of the transplanted segment resulting from an imperfect reestablishment of the circulation. They are not of a regressive character, for both the fibrillæ and the nuclei react normally to stains. This edema may account in part for changes in the size of the transplant.

While in all the transplants there are evidences of regressive changes in small areas, the fibrillæ having undergone hyaline changes or appearing granular, the transplant as a whole remains alive, not being invaded by either leukocytes or round cells. A transplant, examined after fifty-nine days, has practically the appearance of normal tendon and moves readily beneath the skin. The cell mantle has been greatly reduced in size, and the cut surface has a white glistening appearance. But even in cases in which the transplanted segment resembles so closely normal tendon, the three bundles normally found in *the tendo Achillis* have fused so that they can no longer be isolated, and the tendon is larger than the normal one on the opposite side.

The dog from which the tendon was removed for purposes of examination fifty-nine days after operation had been walking for five weeks with practically no limp and without any dropping of the foot, the transplanted tendon having restored completely the function of the leg. In our control animals, in which the segment removed was not replaced, there was never a restoration of function, although, in one case, after forty-five days, there was partial anatomic repair.

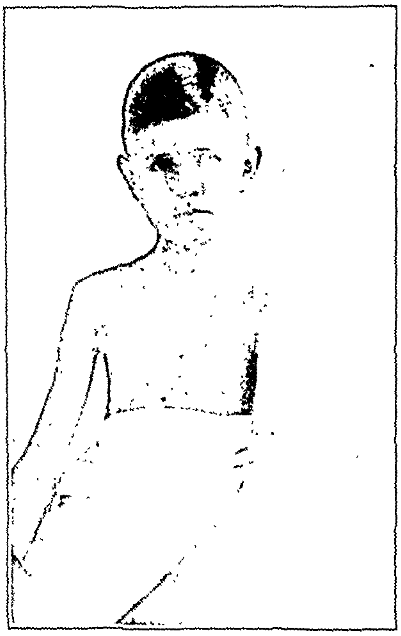

Fig. 11.—Deltoid paralysis of five years' standing following anterior poliomyelitis.

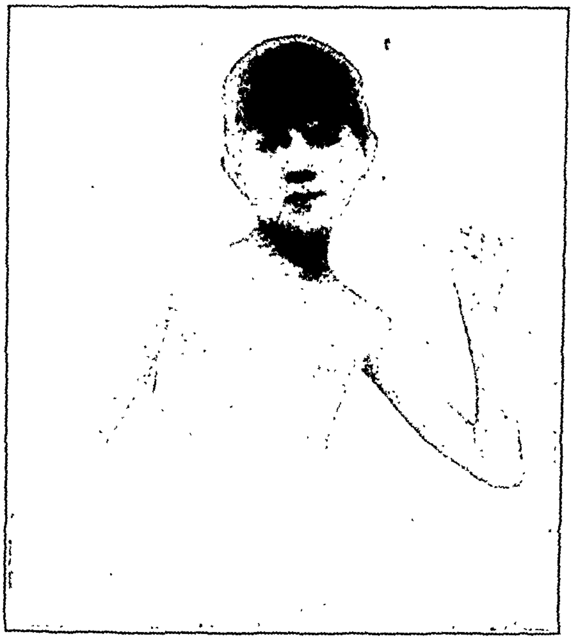

Fig. 12.—Ability to abduct the arm and maintain abduction after trapezius transplantation in patient shown in Figure 11. In this case it was impossible to suture the trapezius as low down on the humerus as desired. A piece of fascia lata was therefore transplanted directly between the trapezius, which had been freed, and the deltoid insertion to act as the tendon of the trapezius muscle.

The staining reactions of the nuclei and fibrillæ of the transplanted segment, the absence of leukocytic and round-cell infiltration, and the absence of any great number of karyokinetic figures, indicate that the transplanted segment acts as a true, viable substitute for the part which has been removed and not as a bridge for developing tenoblasts.

TRANSPLANTATION OF PIECES OF TENDON INTO THE SUBCUTANEOUS FAT OF THE ABDOMINAL WALL

In our second series of experiments, pieces of the tendo Achillis, measuring 1 or 1¼ inches in length, were placed in pockets made in the subcutaneous fat of the abdominal wall. The transplanted pieces were not united by suture to any of the surrounding tissues. They were removed for examination after seven, sixteen, twenty-three, twenty-eight, and thirty-five days. The changes observed in these transplanted tendons differ markedly from those described above, as occurring in tendinous transplants, which assume the function of the segment for which they have been substituted.

There is a tendency for pieces of tendon transplanted into the subcutaneous fat of the abdomen to become progressively smaller. Pieces of tendon, which measured 1 or 1¼ inches when transplanted, were only one-third as long or less when examined five weeks later. Although in this case the transplanted tissue had all of the physical properties of tendon and could easily be identified as such, there were no evidences of any proliferative changes such as occur in transplants which assume the function of the tendon for which they have been substituted. In a tendon removed four weeks after transplantation, the three bundles occurring in the normal tendo Achillis could still be isolated, surrounded by its synovial sheath. After transplantation into the subcutaneous fat, the tendon shrinks to form, in those cases examined some time after the operation, a small ball of tendinous material. These transplanted pieces form with the subcutaneous fat close adhesions, but the line between the tendon and fat is sharply demarcated.

Microscopic examination shows that the fibrillæ and nuclei stain well and that the piece of transplanted tendon may be regarded as viable. There is some leukocytic and round-cell infiltration. The most striking difference between transplants which have assumed early the functions of the segment for which substituted and those which have been placed into the subcutaneous pockets without assuming function, is the absence of any proliferative changes in the peritendineum, of the latter. The peritendineum of pieces of tendon transplanted into the abdominal wall is perfectly passive, there being no effort to form a cell mantle. Apparently there is also no edema of such a transplant. Such a transplant may be compared to a paralyzed limb. It has circulation and is viable, but becomes shrunken and differs in many ways from a transplant which has assumed the function of the tendon for which it has been substituted. Some of these differences may be accounted for by the early establishment of circulation from the end of the muscle, in those cases in which the tendon has been substituted, for a tendon which has been removed. Transplanted tendons which assume function early, do much better than those which are immobilized for long periods of time, both regarding the viability of the transplanted segment and the freedom with which they move beneath the skin. Sutures, such as those recommended by Dreyer or Fritsch, which do not strangulate the tissue, but still insure a union so firm that the tissues cannot be separated by movements begun shortly after the operation, should be employed.

TRANSPLANTATION OF FASCIA

Kirschner, while experimenting on the direct transplantation of tendons, was the first to suggest that fascia might be used to repair defects in tendons. In discussing the possibility of fascial transplantation, he remarks that we have in fascia, especially in the fascia lata with its strong iliotibial band, a tissue which can be easily used in bands of practically any length or breadth, and in almost unlimited amounts without interfering with the function of the structure from which it is removed. These strips may be used either in the form of narrow strips or sewn into the form of a tube uniting the ends of the tendon which is to be repaired.

In determining the viability of fascia, we have transplanted into the subcutaneous fat of the abdomen or under the skin of the thigh either pieces of the fascia lata or of the sheath of the rectus abdominis. The pieces which were transplanted measured ¾ of an inch in length and ½ an inch in breadth. These transplanted pieces of fascia were examined after four, ten, fourteen, twenty-three and thirty-five days. Transplanted pieces of fascia, when not sutured in position, curl up and become smaller than when first separated from the fascial band or aponeurosis. The changes in form and size of the transplanted pieces apparently depend on the direction of the tension planes of the fibers in the piece transplanted. In these experiments the transplanted fascia was not sutured in position, because we desired to subject the transplanted tissue to a severe test, and a line of suture would favor the early development of circulation in the transplanted fascia. As the transplanted fascia curls up, it is necessary to cut the transplanted tissue somewhat larger than the defect to be covered, in order to insure against undue tension.

The fascia examined four days after transplantation was removed from the sheath of the rectus abdominis and placed in the subcutaneous fat of the abdominal wall. After four days, when the dog was killed, the transplant preserved all the characteristics of fascia. It had become somewhat reduced in size, because it was somewhat curled on itself. The fascia had contracted slight adhesions with the subcutaneous fat, but could be moved easily under it. On histologic examination the fibers of the fascia reacted normally to stains. A layer of leukocytes with some round cells surrounds the transplanted tissue, but has not invaded it.

The fascia examined ten days after transplantation was a piece of about the same diameter as that mentioned above. It was removed from the fascia lata and placed on the same fascia at a lower point without suturing. When examined after ten days, the transplanted piece was adherent to the fascia lata by a thin layer of granulation tissue and fibrin. It had all of the characteristics and microscopic features of normal fascia.

Figures 8, 9 and 10 indicate the condition of transplanted pieces of fascia after fourteen, twenty-five and thirty-five days. In Figure 8 the transplanted fascia has been cut parallel to the long axis of its fibers. The subcutaneous fat is adherent to the transplanted tissue, but there is very little reaction about the fascia, but few leukocytes and round cells, none of which have invaded the transplant, being found. Figure 9 represents a cross-section through a piece of fascia examined twenty-three days after transplantation. The fibers of the fascia which are cut transversely stain normally. There is considerable leukocytic and round-cell infiltration in this case at the margins of the transplanted fascia. There has been, however, but little invasion of the transplanted tissue, and this has occurred about the septa separating the different bundles composing the fascia.

After thirty-five days the transplanted fascia has contracted firm adhesions with the subcutaneous fat and has been considerably reduced in size. The piece transplanted still preserves all the physical characteristics of fascia, although it is considerably more resistant than at the time of transplantation. The fibrillæ of the transplanted fascia react normally to stains, preserve their wavy characteristics and are not invaded by leukocytes or round cells. This piece of fascia, thirty-five days after transplantation, although it is somewhat reduced in size, is viable and could be used as a substitute for tendons when repairing defects in the latter.

Fascial grafts have been used in a few instances to transplant a muscle to a new insertion or to correct a deformity, such as a drop shoulder resulting from paralysis of the spinal accessory nerve. Payr, mentioned by Kirschner,[9] has used a piece of fascia lata to correct a congenital ptosis in a boy 12 years of age, after an unsuccessful attempt with the silk-strand method. At the second operation, the scar remaining from the first operation and the silk tendon were removed. A piece of fascia lata measuring 2 cm. in width and 10 cm. in length was then removed and sutured below to the tarsus and above to the frontal muscle, enough tension being maintained to elevate the lid. Another transverse incision was then made, two fingers' breadths above the original wound, and after the skin was undermined the fascia was again sutured to the frontal muscle. The result was almost perfect, as after the operation the opening and closing of the lids is the same on both sides. Rothschild[10] has transplanted with success a piece of fascia lata to correct a functional disturbance, due to paralysis of the trapezius muscle. In this case a piece of fascia lata 20 cm. long and 4 to 5 cm. broad was sutured to the vertebral border of the scapula and to the supraspinous ligament, thus correcting the drop shoulder.

We have transplanted pieces of fascia lata into the hand, when attempting to restore anatomic conditions destroyed as the result of a burn or injury. In the two cases in which we have transplanted fascia into the palm, the grafts have apparently healed for they have not been extruded.

Recently, while transplanting the trapezius to correct a deltoid paralysis of five years' standing in a patient kindly referred by Dr. J. L. Porter of Chicago, we were unable to use the cleido-occipital portion of the trapezius because it was involved in the paralysis. The acromial and spinous portions of the trapezius were then freed, but we could not suture them as low down on the humerus as we desired. A piece of fascia lata measuring 3 inches in length and 1½ inches in breadth was then removed and sutured into the trapezius above and into the deltoid tendon at its points of insertion below. A thin layer of fat was removed with the fascia. The fat was placed next to the shoulder-joint and the neighboring tissues, in order that the transplanted fascia would not adhere to the subjacent structures. In this case a portion of the pectoralis major muscle was freed and attached to the humerus above the deltoid insertion, with the idea that this muscle might aid in bringing the arm upward and forward. The paralyzed deltoid muscle was then imbricated over the fascial transplant being sutured to the trapezius muscle. The wound healed by primary union.

Seven weeks after the operation, the patient could abduct the arm to 70 degrees, and could maintain it in this position for some length of time.

The success accompanying the few cases in which fascia lata has been transplanted directly to form tendons, warrants a more extensive use of it for this purpose, for it has considerable resistance, its elasticity is greater than that of tendon, and its thinness practically guarantees the nutrition of the piece transplanted. We are indebted to Dr. E. Kirk and Dr. A. M. Moody for the preparation of the sections from which the accompanying photo-micrographs were made.

ABSTRACT OF DISCUSSION

DR. LEONARD W. ELY, Denver: Rehn seems to have gone furthest in this line heretofore, but his work is characterized largely by scolding and by credulity. As I understand it, he implanted a piece of tendo Achillis in the walls of the abdomen, and because one layer was better developed than another, he deduced that motion was necessary.

He believed the story of some civil engineers who had been in China and had heard of this reparative tendon work there. There are many branches of scientific knowledge which seem to be so limited in application that we wonder where their particular value will come in, and I had been inclined to look at this tendon and fascia transplantation more as an interesting abstract study than anything else. Rehberg is reported in the *Berliner Klinische Wochenschrift* as having trephined for traumatic epilepsy, removed the thickened dura and transplanted fascia lata in its place, with great success. No praise for such work as this of Dr. Lewis' can be too high.

DR. KENNETH A. J. MACKENZIE, Portland, Ore.: I think we are all agreed that so far as treatment of traumatisms which have led to the creation of big gaps in tendons the problem is solved by this procedure. I notice that in the abstract of this paper reference is made to the use of tendons to fill gaps created by trauma in the case of nerves, although I do not think that Dr. Lewis made any reference to this in his paper.

It would seem to me that the fact that has been well brought out, that when the tendon is implanted remotely in the tissues no cellular infiltration takes place in the graft and no histologic changes except apparently normal changes, would lead fairly to the conclusion that the tendon might be very useful as a conduit for nerve flaps or grafts, the tendon being used as a container or carrier. I should like to have heard some reference in the paper as to what has been done with the tendon in this connection. Those who are confronted with cases in which nerves have been destroyed over long stretches will find a good deal of comfort in the fact that even in the case of very large gaps in nerves, bridging may be done by the use of very long flaps when properly protected.

In a case that I reported two years ago the sciatic nerve was the seat of malignant tumor, and the entire trunk of the sciatic was resected. Flaps from the popliteal branches were lifted up at different times two weeks apart; these flaps were 19 inches in length, the gap in the sciatic being 12 or 13 inches in length. The ends of these flaps were brought up to the truncated end of the sciatic at the lower point of section, one popliteal end was anastomosed into the other and the slender flaps bridging the gaps were sutured into the sciatic trunk above, the grafts being placed in separate muscular beds by suture. At the end of eighteen months the functional results were so satisfactory that the man could walk and work as well as formerly without aid to locomotion, although, of course, there was a permanent and extensive impairment of the sciatic sensory area.

DR. JOSEPH KURTZ, Los Angeles: Since 1903 I have practiced rather extensively tendon transplantations. In 1903 I had the pleasure of being in Europe with Lange of München and Wolfius of Heidelberg, the two men who did more for tendon transplantation than all the rest of the surgical world. The art of transplantation, if I may say so, has long since passed its experimental stage; it is as perfect as an amputation or a laparotomy. We know now perfectly well what we can do. We take a healthy tendon and transplant that into a weak tendon, or part of a healthy muscle into a muscle that is weakened either from paralysis or injury and fortify it.

The tendon or muscle which is fortified by transplantation of healthy tissue, becomes practically healthy normal muscle or tendon. The change in the tonicity of the tendons is remarkable. You know that a diseased tendon is flabby; it has lost its luster, its ivory shine, and as soon as you have implanted a healthy or part of a healthy tendon into such a diseased tendon, you can notice after three or four weeks, if you should get the opportunity to see it, that this fortified, originally diseased tendon looks just as bright as the one that has been implanted into it.

Now the greatest use of tendon transplantation is made in those conditions which are left after cases of anterior poliomyelitis. How long is it since we have really considered that a paralytic club-foot is curable? I do not believe it is more than five years. We can transplant the adductors into the abductors, or *vice versa;* the flexors into the extensors, or *vice versa*, in club-foot; and we can do the same thing with the arm, as has been explained, with perfect results as to function. Within one month the function, if not perfect, is at least good. Within a year, I venture to say, after operation, the functions in the originally diseased tendons become as good as in any of the other tendons.

DR. DEAN D. LEWIS, Chicago: In the abstract we referred to the use of fascia in the form of a tube, which might be used in the repair of nerve defects; the ends of the fascial tube being sutured over the ends of the nerve, thus forming a tunnel of living tissue through which the regenerating nerve fibers could pass.

I admit that the method of tendon transplantation or transfer which Dr. Kurtz was discussing is not in an experimental stage. The work of Vulpius and Lange has shown this. Lange's periosteal silk strand method is an accepted and most valuable procedure in treating paralysis following poliomyelitis. But in traumatic cases or the results of sloughing of infected tendons, bad results may follow the use of the artificial silk tendon. Lange himself says in a recent article that in these cases the silk tendon may be contra-indicated and that the method of direct fascial transplantation may be the one of choice.

Graves' Disease at the Age of 10.—The case of J. W. H., boy, aged 11, who exhibited undue prominence of the eyes at the age of 10, is reported by W. Essex Wynter (*Proc. Roy. Soc. Med.*, June, 1911). When admitted to Middlesex Hospital in March, 1911, there was obvious proptosis, with all the usual signs. The thyroid gland was enlarged, both isthmus and lobes; the fingers when extended, exhibited fine tremor; the skin was moist and flushed and about the hands and neck showed yellowish pigmentation. There were no cramps, but the patient had faint attacks, flushes and occasionally showed some temporary puffiness of the face. There was incontinence of urine; the urine was clear, amber-colored, acid, specific gravity 1,015 and contained a trace of albumin. The pulse ranged from 92 to 124.

THE INFLUENCE OF CLIMATE ON MIDDLE-EAR DISEASES AND THEIR PREDISPOSING CAUSES *

JAMES J. PATTEE, M.D.
PUEBLO, COLO.

The intimate relationship between diseases of the middle ear and abnormal conditions in the nose and throat has furnished a theme rich in interest for the otologist on the one hand, and no less attractive to the rhinologist on the other. Both have studied this relationship, which has strengthened as the work has progressed. The former arbitrary separation of diseases of these organs having been outgrown, there has arisen between them a mutual dependence, of which reports of modern progress are full and convincing. That the nose is the seat of numerous predisposing causes of middle-ear diseases is generally admitted to-day, whereas a few years ago no such relationship was dreamed of. In the symposium under discussion, a consideration of climate which lost sight of the interdependence of affections of these mutually related organs would entirely fail in its comprehensiveness.

Permit me, at the very outset, to make it plain that I am not dealing with climatic treatment of middle-ear disease. Climatic treatment, *per se,* like any other treatment *per se,* would fail to meet adequately all of the indications of any class of cases. The direct influence of climate alone on established middle-ear disease is very slight, whereas the indirect influence on the predisposing causes is considerable. As the majority of middle-ear diseases are secondary, so climatic influence is greatest indirectly. It is not my aim to underrate the importance of the surgical treatment of predisposing conditions in the nose and throat. On the contrary, I accept them all, if indicated. Neither is it intended to minimize the merit of constitutional or local treatment. I wish merely to present briefly a few such observations and opinions as will emphasize the importance of climate from a prophylactic and therapeutic standpoint. From a mere viewpoint of definite cure of chronic cases of middle-ear disease, climatic influence seems not to take a high place, since few patients are cured by it alone, compared with cures obtained from other lines of treatment. It seems to me, however, that reports of cures of these convey an inadequate idea of the influence of climate on conditions admittedly predisposing to middle-ear disease.

That there is enormous worth in intranasal surgery, removal of tonsils, adenectomies, etc., is not denied, but when it is remembered that complete obstructions in both nostrils may continue for some time without affecting the hearing; that the pernicious furor to attack every irregularity within the nose has led to a large amount of unwarranted operating in the nose and throat; that intranasal operations have frequently been done on patients whose conducting apparatus had already been injured by pathologic processes; that adenoid operations have often failed to ameliorate the symptoms for which they were performed; that we can have middle-ear inflammation and suppuration without enlarged tonsils and adenoids; when we recall facts like these, we can begin to rate, at something like their true value, other lines of treatment and question whether surgical operations are always of the transcendent importance assumed.

While it is impossible, in the brief time at my disposal, for me to take up a discussion of climate in general, I may enumerate a few of the characteristics of the climate, altitude and environments of Colorado, New Mexico and Arizona and the influence they produce on the body, and leave to your judgment the effect of opposite conditions. This portion of the Rocky Mountains has a moderate temperature and a decidedly dry atmosphere. It varies in altitude from 4,000 to 9,000 feet with numerous mountain peaks from 10,000 to 14,000 feet, the temperature varying with the altitude. My personal observations are drawn from a residence of five years in western New Mexico, very near the Arizona line, at an elevation of 6,000 feet, and seven years in southeastern Colorado at an elevation of 4,700 feet, both of which might be classed as moderately high elevations. The air is dry, having a low degree of absolute and relative humidity. It is pleasant, tonic and stimulating, with a minimum of those properties that depress and debilitate. There is a maximum of sunshine and the sun's rays are intense. The atmosphere contains few impurities. Owing to good natural drainage, the desiccating action of the atmosphere, and the rarefaction of the air and intense solar heat, the soil dries rapidly, and bacterial activity and multiplication are strongly inhibited. Solly, in his admirable textbook on climates, states that "the air is aseptic and antiseptic." A verification of this statement is found in the manner in which the Mexican preserves his beef and mutton. Pieces of meat are strung on a line and dried in the sun as we dry laundry. His *carne* receives no other treatment for its preservation. Animals die and decompose on the plains, producing but slight odor. The offensive malodorous, nauseating breath of atrophic rhinitis loses much of its unpleasantness. The properties of the atmosphere and sun that cause these conditions, inhibit the action of bacterial infections of the nose, throat and upper respiratory tract, as well as infections in general, and hence indirectly favor the integrity of the ear.

Dr. W. Freudenthal[1] has said, regarding the evil effects of dry, foul, overheated living-room air as a cause of nasopharyngitis:

> If we compare our mode of living with that of a hundred or two hundred years ago, we must confess that we have returned to a very ancient style of living. We have become, *mutatis mutandis,* actually cave-dwellers again. In a ten by fifteen room the average human being passes twenty-three of the twenty-four hours of the day, or even more. The room is nothing but a cave-dwelling, with the exception that it is tightly closed from all sides during the greater part of the year. It makes little difference whether we call this cave a sitting-room in a fashionable house, or whether we term it a sweat-shop. The difference is only in degree. The room is, as a rule, tightly closed against the invasion of fresh air.

Although some of us of the dry and sunny Southwest may not ventilate as we should, most of us live in strong contrast to the conditions above quoted. The pure air, the stimulating breezes, the few mists, fogs and clouds and the great number of sunny days are constantly inviting people into the open and even lead them to sleep out of doors, both summer and winter. The sleeping-porch and the tent-house, which originated here, have done so much for the prevention and cure of nasal, throat and respiratory affections that their service is no longer limited to this region.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Freudenthal, W.: Some Hints on the Treatment of Chronic Nasopharyngeal Catarrh, William Wood & Co.

That the inhabitants of the region under discussion do have colds is not denied, but I have repeatedly been told by patients that their "habit of catching cold" in the East had left them since coming here. This is particularly true of those who sleep on porches or within tents. Fortunately for our people, the umbrella, rubber overshoes, raincoats, etc., which pamper our bodies and act on our *pars minoris resistentiæ,* are rarely used. When we remember that dirty streets, foul air, acrid vapors, overheated rooms, cloudy weather, and wet walks and soil are at a minimum, and that there is a maximum of bright clear days, a pure atmosphere and a dry soil, we can appreciate that in this locality many of the conditions predisposing to colds and indirectly to middle-ear disease, are wanting.

The atmospheric properties are stimulating to the respiratory, circulatory and nervous systems. The vasomotor nerves are, therefore, generally in a healthy state and hence the body resists taking cold. There are two theories regarding the etiology of cold: one, that the cause is an infection; the other, that there is a vasomotor change consequent to exposure, environment, etc. Whether one inclines to the former or to the latter view, I am certain of the fact, based on practical observation as well as on theoretical considerations, that acute colds and acute inflammatory conditions of the nose, throat and ear prevail here with considerable less than average frequency.

Adenoids have been attributed to nearly everything. Although there is much lack of uniformity of opinion on the multitudinous causes generally set forth, I believe that the majority of observers are in accord with the theory that frequent colds, damp, cold, cloudy, changeable weather and badly ventilated, overcrowded rooms increase the percentage of these vegetations. Granting that this is true, it follows that our climate, habits of life and environment naturally mitigate the harmful influence of these causative factors.

Nasal obstructions are of two varieties, hard and soft. The hard variety includes pathologic conditions in the osseous and cartilaginous structures. Except in cases of very moderate degree, they require surgical correction. Climate, unaided by other accepted methods of treatment, could have no trustworthy effect on the real condition in bad cases, although it might change the symptoms considerably, and, I am sure, if judiciously selected, it would improve accompanying conditions, increase the patient's comfort and enhance the postoperative results.

On various occasions, I have left my practice for a course of study in, or visit to, some of the cities of low elevation and damp climates. I have been strongly impressed with the fact that soft tissue obstructions are much less general and are of a milder grade in a dry than in a humid climate. Acute purulent rhinitis in children almost never exists, and acute obstructive conditions of the soft parts are much less severe. The red, swollen, boggy, discharging condition of the mucous membrane and underlying spongy tissue occurs much less frequently in the child, and there is a corresponding decrease of chronic enlargements with accompanying stenosis in the adult.

The lamented Dr. Solly first called our attention to the shrinkage of the mucous membrane and the underlying vascular and glandular tissue with coexisting decrease of nasal discharge. These facts have been impressed on me in clinics and in case histories. My experience with and impressions from the use of cocain and adrenalin solutions were obtained in Vienna and London. The shrinkage caused by their application to the mucous membrane was much less marked and fewer cases responded to their use in Colorado than in those cities or Chicago.

The absence of these obstructive conditions affords better drainage and ventilation to the nose and ear, and may entirely relieve all the symptoms unless hard obstructions exist, and even then their absence would ameliorate the effect. This increased nasal space is beneficial to respiration and drainage and, hence, indirectly to the maintenance of normal hearing. The majority of diseases of the middle ear either occur or begin in childhood when the ear is least in condition to stand harmful influences. Even the adhesive process of later life has its foundation laid during the tender period of childhood. I am convinced, from the examinations for the public schools, that otitis media is less frequent among children here than in a damp climate. Acute tubotympanic catarrh seems to be less frequent and of shorter duration and less inclined to recur. This is due to greater nasal and tubal lumen, an advantage of great importance to the child, whose anatomic and physiologic conditions directly facilitate tubal obstruction. The horizontal tube, the increased vascularity of the underlying mucous membrane, and the increased physiologic activity of the child, coexisting as they do, afford adverse conditions which may, by a very slight change, entirely complete the tubal occlusion with all its consequent damage to the ear. The removal of adenoids, tonsils, etc., employed everywhere for the improvement of these cases, seems to improve them more in a dry than in a humid climate.

Climatic influence on the prevalence and character of acute catarrhal or acute suppurative otitis media, depends on the cause. For instance, it might have very little effect on otitis complicating scarlet fever or measles, whereas its influence on the frequency and severity of otitis from cold in the head, hypertrophic rhinitis or nasopharyngitis would be considerable. In the former group of affections, the percentage of cases might be quite as great in a dry, elevated atmosphere as elsewhere, in strong contrast to the percentage in the latter group, which would be considerably less.

Dr. James Patterson[2] of Colorado Springs states that patients suffering from chronic suppurative otitis media "come to Colorado, of their own accord, yearly because they find the discharge lessens and their general condition is greatly improved by doing so." I have seen a few cases in which remissions were longer and in which improvement on changing from a humid to a dry climate simulated that experienced by some in a damp atmosphere when the weather changes from a humid, cloudy condition to a clear, dry atmosphere. In cases of suppuration of the middle ear without bone necrosis which continue to discharge despite the removal of the adenoids and tonsils, the patients should try climatic treatment.

In the southwest, tuberculous patients are numerous. The tuberculous and non-tuberculous suffer from the same middle-ear diseases. The affections in the tuberculous, however, and by that I mean the pulmonary form, are modified by the constitutional condition of the individual and by the relative increase in the number of cases that acquire tuberculosis of the middle ear by auto-infection. Ordinarily, suppurative otitis media in the tuberculous runs an uncommonly chronic course. Many of the patients improve on changing to a dry climate. Comparatively few of this number fail to derive benefit from accompanying aural affections. Of all ear affections, there is none in which climate is of such comparative reliability as in those accompanying pulmonary tuberculosis in which the general condition will support the infection. Those early cases with sufficient vitality to improve do infinitely better here than elsewhere, owing to the stimulating effects of the environment, altitude and atmosphere on the general health of the individual, thus indirectly alleviating the ear disease. A necrosis of the temporal bone that would seem trivial in a healthy individual, might be serious in the tuberculous patient.

---

[2] Patterson, James: The Climate of Colorado Etiologically and Therapeutically Considered, Laryngoscope, September, 1908.

Tuberculosis of the middle ear is so insidious in its onset, so complex in its course and so disastrous in its ultimate effects, that an early diagnosis and prompt treatment are paramount. The favorable opportunity for the arrest of tuberculous otitis, even more than in other forms, is in the beginning. The successful treatment of tuberculous infections hinges on the development of an immunity which, in turn, depends on healthy constitutional conditions. Immunity is obtained by furnishing the patient freely with good food, pure open air day and night and a maximum of sunshine. The effect of all these agencies is enhanced in the Rockies. There is surprising increase in appetite, weight, hemoglobin and metabolism. Dr. De Forest Willard[3] says: "For thirty years, even before Koch's discovery of the tubercle bacillus, I have persistently advocated and practiced the fresh air method of treatment for tuberculosis of the hip and spine and have never known it to be without benefit." Precisely the same is true of the open-air treatment of tuberculous otitis, and there is no place under the sun quite so favorable for ideal open-air treatment as is the Southwest. Here the climate, by its beneficial influence on the patient and its destructive action on the tubercle bacilli, affords the most favorable opportunities for ideal open-air treatment. Here the climate has a powerful influence on the treatment, whether it be local or surgical.

In case of hypersecretion with turgescence of the mucous membrane and underlying spongy tissue of the tube and nasopharynx; in secretory catarrhal affections in which, despite the removal of nasopharyngeal obstructions, ample tubal nasal lumen cannot be obtained; in patients operated on for obstructions without improvement in hearing, on account of an unhealthy state of the mucous membrane; as an accessory treatment to intranasal surgery and as an aid to the constitutional and local treatment of catarrhal otitis media, climate plays an important rôle. A large percentage of cases of secretory and dry catarrhal otitis media, which develop in a damp, changeable climate and which are aggravated by inclement weather, improve in a dry climate and may be permanently arrested, unless there has already taken place too much hypertrophy and atrophy of the sound-conducting mechanism.

Pulse-Rate in Male and Female.—A. H. Stewart says in the *Medical Record* that in man, as in nearly all animals, the pulse-rate is slightly slower in males than in females, in the proportion of 72 per minute for men and 80 for women. But as slowness of pulse, like slowness of respiration, nearly always goes with increased weight, the difference is probably no greater than would naturally be expected. In old age woman's pulse-rate is inclined to increase slightly more than man's.

HOW FAR MAY CONDITIONS IN THE NOSE AND THROAT BE RESPONSIBLE FOR MIDDLE-EAR DISEASES? *

WILLIAM R. MURRAY, Ph.B., M.D.
Professor of Rhinology and Laryngology, University of Minnesota
MINNEAPOLIS

I have confined myself to a discussion of the extent to which diseased conditions of the nose and throat are either directly or indirectly a factor in the production of diseases of the middle ear.

That involvement of the middle ear is, in a great majority of cases, due to a diseased condition of structures contiguous to the Eustachian tubes is a fact on which all otologists are agreed. It is not a question, then, as to whether diseases of the nose and throat may be responsible for ear involvement; that question was quite definitely settled by Wilhelm Meyer[1] in 1870 when he published his paper on "Adenoid Vegetations in the Nasopharyngeal Cavity" and pointed out the effects of such growths in the causation of deafness. The questions at present are: To what extent are nasal and nasopharyngeal lesions responsible for deafness? What form of nasal and nasopharyngeal abnormalities are responsible for such ear complications. And are we attributing too little importance to the upper respiratory tract as an etiologic factor in the production of otitis media?

If there is a dark chapter in the history of otology, I think you will all agree with me that it is in the unsatisfactory and unsuccessful results with which we have to be content in the treatment of many of those cases of advanced adhesive processes of the middle ear attended by marked impairment of hearing, and, for that reason, another discussion and further emphasis of this clinical relationship between the upper respiratory tract and diseases of the middle ear seems advisable, although I regret that I have nothing new to present to you.

That impaired hearing is an extremely common affliction is evident, and of the different forms of deafness catarrhal otitis media and purulent otitis media furnish the vast majority of cases. Otosclerosis is not considered within the province of this paper, as, so far as I am aware, no evidence has been presented that it is due in any way to nasopharyngeal diseases or that any benefit is to be obtained by treatment directed thereto. Moreover, true otosclerosis furnishes such a small proportion of cases of deafness that it does not affect the importance of the subject under discussion.

Involvement of the middle ear may occur in the following manner: 1, through the external auditory canal, by involvement of the membrana tympani; 2, by the blood-vessels and lymphatics, and 3, by way of the Eustachian tubes. In considering the method of involvement of a middle-ear disease, it should also be remembered that any factor that impairs the vitality of the patient will be a contributing factor in the onset and progress of a middle-ear disease. I think it a conservative estimate to say that in 90 per cent. of all cases of catarrhal deafness and purulent otitis media the source of the involvement is by way of the Eustachian tubes.

Weil[2] examined 5,905 children and found that about 30 per cent. had some degree of deafness. Bezold[3] found, among 3,826 children, that 20 per cent. had deafness. Cheattle[4] examined 1,000 school children and found 335 had a discharge from one or both ears. Preysing[5] examined 100 children (post mortem), aged 1 day to 3 years, deaths due to various causes, and found that eighty-one showed middle-ear disease.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Meyer: Med.-Chir. Tr., London, 1870, liii.

[2] Weil: Quoted by Politzer, Diseases of the Ear.

[3] Bezold: Quoted by Politzer, Diseases of the Ear.

Miller[6] examined fifty cases (post mortem), and thirty-seven showed pus in one or both ears. Meningitis was found in ten cases and eight of them showed pus in the middle ear. Randall[7] states that one-third of all adults are deaf in one or both ears and that among school children 25 per cent. are deaf. Bardes[8] estimates that two-thirds of the people have an aural defect. Barth[9] places the percentage of all children having otitis media during the first year of life as high as 80.

Bryant[10] states that the middle ear is involved in 98 per cent. of all cases of deafness; that the middle ear alone is involved in 84 per cent. of the cases, and that chronic middle-ear catarrh furnishes 69 per cent. of all cases of chronic deafness. Bürkner[11] states that among every 100 cases of ear disease, 67 per cent. are cases of middle-ear disease.

Diseased conditions in the nasopharynx are a prolific source of involvement of the Eustachian tubes and cavum tympani which may be caused in the following ways:

1. By mechanical obstruction of the osteum of the tube by large masses of adenoid tissue or by smaller masses situated laterally in the nasopharynx and encroaching on the orifice of the tubes and interfering with ventilation and drainage from the middle ear. This mechanical theory to account for the involvement of the Eustachian tubes by adenoid masses is one that has been quite generally accepted by otologists in the past. I believe that its importance has been greatly overestimated and that an extension of the adenoid mass to the opening of the Eustachian tube is the exception.
2. By direct extension of an inflammatory process from the nasopharynx to the pharyngeal opening of the Eustachian tube thus causing obstruction and infection from involvement of the tubal mucous membrane.
3. By entrance of mucous and infected material into the fossæ of Rosenmüller and into the pharyngeal opening of the Eustachian tubes, due to the presence of hypertrophied glandular tissue or to a chronic hypertrophic or atrophic pharyngitis.
4. By interference with the action of the tubal muscles, the levator palati and tensor palati, the proper and normal function of which is so necessary in maintaining normal ventilation and drainage of the middle ear.
5. By the presence in the fossæ of Rosenmüller of accumulations and adhesive bands, often the remains of former adenoids, or due to operative measures for the removal of adenoids.
6. In occasional cases, proper passage of air into the middle ear may be interfered with by paralysis of the fauces, resulting in an interference with the action of the tubal muscles.
7. By tumors of the nasopharynx.
8. By blood-vessels and lymphatics.
9. By adhesions of the soft palate to the pharyngeal wall.

The presence of hypertrophied glandular tissue in the pharynx and epipharynx is the most frequent source of middle-ear disease. That a considerable proportion of children, as well as many adults, are afflicted with adenoids, is a fact well known not only to the medical profession but to the laity. It is also a well-recognized fact that disease of the middle ear among children is very frequently due to adenoids, but I do not believe that the fact is sufficiently emphasized by otologists that many cases of deafness, which apparently have their origin in adult life, are due to the presence of adenoids during the early years of the life of the individual. While ear involvement is the most frequent complication of adenoids in children, yet it frequently happens that the involvement of the Eustachian tubes and tympanum is mild in character, not attended by pain or marked impairment of hearing, and is so insidious in its onset that it escapes attention. These repeated attacks of Eustachian salpingitis may be the cause of what is apparently a beginning chronic catarrhal otitis media in adult life. Kopetzky[12] found that 27 per cent. of adult cases showed the origin of the ear involvement to be in childhood. Barbarin[13] found that out of 100 cases of chronic middle-ear suppuration among adults, forty-two were traceable to infancy or childhood. The statement of Makenzie that the discovery of adenoids by Meyer had saved 100,000 people from deafness is a conservative one. A reference to the published statistics of different writers on the occurrence of middle-ear disease, as a complication of adenoids, will show a great lack of uniformity as to the frequency of this complication. This may be due, in some cases, to the class of patients from which the material for examination is obtained, or it may be that ear complications occur more frequently in some countries, or in certain portions of a country, than in others, or it may be due to the manner in which such examinations are made. If a careful objective examination were made in those cases of adenoids where there are no subjective symptoms or history indicating ear involvement some change would be found in the appearance of the membrana tympani in a very large proportion of cases, indicating some interference with the ventilation of the middle ear. Intermittent attacks of deafness in young children, occurring in connection with an acute coryza, are due to acute congestion of existing adenoid tissue with temporary involvement of the Eustachian tubes. Recurring attacks of subacute otitis media, usually mild in character, where the child complains of ear-ache for a short time, are due to temporary closure of the Eustachian tubes as a result of adenoids. Exclusive of the ear complications of the acute infectious diseases, a vast majority of the cases of acute purulent otitis media in children is due to adenoid tissue. In many of these cases there is no history of nasal obstruction or of mouth breathing and the only subjective symptoms are the attacks of ear involvement and of acute coryzas.

Arslan[14] found, in a series of 426 cases of adenoids, that 59 per cent. had ear complications. Barth[15] found 30 per cent. of adenoid patients had middle-ear disease. Wood[16] found 42 per cent. of adenoid cases had ear complications (149 cases). Kerrison[17] examined fifty children who had adenoids and found forty-five of them showed some evidences of aural disease, many of the cases showing greater retraction of the membrana tympani than usually accompanies tubal obstruction in adults.

From an examination of the records of 600 cases of adenoids, I found middle-ear involvement in 31 per cent. In my cases, only such ear complications were

noted as were revealed by subjective examination. Barstow[18] reports that out of fifty-seven cases of adenoids in adults, twenty-five of the cases had aural complications. I have also called attention[19] to the frequency of adenoids in adults and to their influence in the production of middle-ear disease.

The presence in the fossæ of Rosenmüller of accumulations of lymphoid tissue, or of adhesive bands, is a frequent source of middle ear involvement. In many cases these accumulations in the fossæ are the remains of adenoid tissue present during childhood. Logan[20] has called attention to the presence of chronic epipharyngeal periadenitis in adults as a cause of middle-ear disease. He has shown, by pathologic examination, that the disease involves not only the glandular structure but extends to the muscular, vascular and connective tissues and considers it of special importance with reference to the tubal muscles. He reports 284 cases. between 25 and 59 years of age, and of the 284 cases, 210 had chronic progressive deafness; twenty-four were subject to recurrent attacks of acute otitis media; seventeen had chronic suppurative otitis media; thirty-three had no ear complications. Of the 210 cases of chronic progressive deafness, 182 showed improvement after the operation. Of the twenty-four cases of recurrent acute otitis media operated on, sixteen have had no recurrence. Of the seventeen cases of chronic suppurative otitis media, five have had no recurrence since the operation. The author found that these masses exist in greatest abundance in the fossæ of Rosenmüller. Emerson[21] frequently found degenerated tissue in the fossæ and showed that it is an important factor in causing or maintaining morbid conditions in the middle ear. Hays,[22] in a series of fifty cases of chronic catarrhal otitis media, varying in age from 5 to 70 years, found abnormalities of the nasopharynx in thirty-nine cases, and in thirty-three of them there was a diseased condition of the fossæ of Rosenmüller. He is of the opinion that adhesions are present in the fossæ in all cases of chronic catarrhal otitis media. Packard[23] has also called attention to the presence of adhesions in the nasopharynx and their influence on the middle ear. Jervey[24] has forcibly called attention to this condition and states that these formation bands in the fossæ consist apparently (1) of mucofibrous bands, or webs, generally in a perpendicular plane to the long axis of the fossa, and (2) of masses of granulation tissue, or hypertrophied glandular tissue, similar to adenoids, lying above, between and below these bands. He usually found them in adults and considered them as residua of old adenoids. Bryant[25] and others have emphasized the etiologic importance of adherent bands in the fossæ of Rosenmüller in the production of chronic catarrhal ottitis media.

Diseased faucial tonsils are an important etiologic factor in the production of disease of the middle ear, either directly or indirectly causing involvement of the Eustachian tubes. I believe this relationship between disease of the faucial tonsils and the middle ear has not been sufficiently emphasized. It is not at all unusual to have patients volunteer the information, immediately after a tonsillectomy under local anesthesia, that they can hear better, and this sometimes occurs-with patients who have made no complaint as to their hearing and in whom a previous history has elicited no subjective symptoms indicating an ear complication. As diseased faucial tonsils are so frequently associated with abnormal conditions in the nasopharynx it is difficult to say to what extent the tonsils are the direct cause of such ear involvement. An associated nasopharyngitis may be, and frequently is, due to diseased tonsils and the secondary pharyngitis usually shows marked improvement on removal of the offending tonsils. The variety of diseased tonsils which I have found most likely to be the contributing cause of a middle-ear complication, is the deeply embedded diseased gland so frequently present in adult life and these tonsils may be the means of causing or maintaining a middle-ear complication as follows: by direct extension of a chronic inflammation to the orifice of the Eustachian tube; by direct pressure backward and outward in the tonsillar fossa, thus interfering with the ventilation of the tympanum; by maintaining a constant source of infection from which pathogenic microorganisms or infected mucus may gain entrance to the tubes; by interfering with the physiologic action of the levator palati and tensor palati muscles; by causing venous congestion of the blood-vessels, thus causing a constriction of the caliber of the Eustachian tube and interfering with the entrance of air into the tympanum; by infection through the blood and lymph streams.

Attention has been called to the effect of diseased faucial tonsils on the middle ear by Myles,[26] Reik,[27] Hays[28] and others. Hays, in his study of fifty cases of chronic catarrhal otitis media, found that in ten cases the faucial tonsils indirectly affected the ears and adds that the tonsillar condition was in all cases associated with some pathologic condition in the nose and this association produced abnormal conditions in the nasopharynx.

The clinical relationship of diseases of the middle ear to diseases and abnormalities of the nasal passages must be considered an indirect rather than a direct one. Reference to the literature of the past ten years will show a great diversity of opinion as to whether an abnormality of the nasal passages is responsible for an ear involvement. That a nasal obstruction, if unaccompanied by an inflammatory condition posterior to it and by a normal nasopharynx, will not be responsible for disease of the middle ear is probably true. That the nasal passages have too frequently been held responsible for ear diseases and that the nasopharynx has escaped its share of responsibility is also true. We are forcibly reminded of this whenever we are consulted by that numerous class of patients whose nostrils have been subjected to such radical operative work, for the relief of a middle-ear involvement, that there is hardly a normal functionating structure left within the nasal passages.

The presence of a nasal obstruction does not always mean that it is a factor in a middle-ear involvement. A marked deviation or irregularity of the nasal septum may be of such a character that it interferes but slightly with either the inspired or expired current of air. An obstructive lesion situated low down in the nostril may so interfere with the expired air that the nasal secretions accumulate and may give rise to a nasopharyngitis, or a violent expiratory effort in blowing the nose, may drive the infected secretion into the Eustachian tubes and cause an involvement of the middle ear. I believe it may be stated, as a general rule, that any nasal lesion that is capable of causing a nasopharyngitis, or is attended by a purulent discharge, or so interferes with drainage of the nasal passages that the accumulated secretions may gain entrance to the Eustachian tubes, may be a cause of middle-ear disease.

A purulent discharge from an infected nasal sinus is a constant source of danger to the middle ear. This is particularly true of the sphenoid and posterior ethmoid sinuses the discharge from which passes backwards into the nasopharynx and is the cause of a nasopharyngitis, which, in turn, may extend to and involve the Eustachian tubes, or the purulent discharge may be blown into the tubes and cause an otitis media. Cobb[29] believes that in the treatment of chronic catarrhal deafness, the key to the situation is that most common of all causes of nasal catarrh, obstruction to drainage from the ethmoid cells, and he believes that the active factor in this obstruction is a peculiar formation of the middle turbinate. Jackson[30] of England believes that caries of the superior and middle turbinate and ethmoid cells is frequently responsible for middle-ear disease and quotes Woakes, who lays great stress on the association of deafness with atrophic changes in the ethmoid. Woakes[31] states that out of 921 cases of deafness, one in three and one-half (274 in number), showed also the presence of ethmoiditis. Of those showing both deafness and ethmoiditis, one in four had tinnitus only, one in twenty-five had vertigo only, and one in fourteen had both tinnitus and vertigo. Of the 647 of the 921 cases in which deafness was not associated with ethmoid disease, one in nine had tinnitus only, against one in four; one in 64 had vertigo only, against one in twenty-five, of the preceding 274; and one in thirty-two had both tinnitus and vertigo, against one in fourteen of the same group. Dundas Grant,[32] in his address before the American Academy of Ophthalmology and Oto-Laryngology in 1906, in discussing the question as to whether nasal obstruction, as such, can cause or keep up catarrhal conditions of the middle ear, referred to the report of Röpke of Solingten, who investigated the question of the influence of nasal obstruction on the ear and found that in a large majority of cases the hearing power was lower on the side on which the nose was obstructed. If there was lowered hearing power on both sides, it was almost invariably the ear of the side on which the nose was obstructed which was the worse. A further outcome of the investigations was that the hearing (in the majority of cases) was improved or even became normal within a few weeks after operative correction of the nasal obstruction, without catheterization or any other therapeutic measures being employed. He attributed the ear involvement to accumulation of secretions behind the obstruction and to their being driven up the Eustachian tubes. Grant does not refer to the character of the ear involvement present in Röpke's cases; a point of great importance in a consideration of the excellent results recorded by Röpke from nasal operation.

Atrophic rhinitis, usually accompanied by atrophic pharyngitis, is, in a considerable percentage of cases, complicated by middle-ear disease. Such ear involvement is due (1) to the atrophic condition of the mucous membrane of the pharynx, (2) to the patulous openings of the Eustachian tubes, as a result of the atrophic process, and (3) to the presence in the region of the tubal openings of crusts and mucopurulent discharge which may easily cause infection of the middle ear. Sendziak,[33] from a study of 1,142 cases of atrophic rhinitis, found aural complications present 166 times (14.5 per cent.). Wyss[34] found aural complications forty-seven times in sixty cases. Jurasz[35] found aural complications in twelve out of 170 cases of ozena.

Middle-ear involvement is one of the frequent complications of the acute infectious diseases of childhood. Statistics show that scarlet fever is complicated by ear involvement in from 12 to 30 per cent. of the cases, depending on the severity of the epidemic, and that measles is also complicated by ear involvement in about the same proportion. Statistics also show that a large proportion of those intractable cases of chronic purulent otitis media and of total deafness originate during an attack of the infectious diseases. What is the relation between the infectious diseases of childhood and diseases of the middle ear? During the acute diseases, most likely to be accompanied or followed by ear complications, such as scarlet fever and measles, there is present an acute inflammation of the nasopharyngeal structures which, in connection with the lowered resisting power of the patient and the short, wide, more nearly horizontal Eustachian tube of the young child, favors infection of the middle ear. In addition to this, if the patient has [illegible] obstruction, such as adenoids, which [illegible] inage or ventilation through the Eustachian tubes and furnishes a constant source of infection from microorganisms, there is added a very great source of danger to the middle ear. Moreover, after the onset of an acute purulent otitis media, during the course of an infectious disease, the presence of adenoids will be a most important factor in the continuance of the purulent discharge with resulting permanent deafness. In connection with this influence of adenoids on the middle ear during the course of the exanthemata, the investigations of Leland are of interest. Leland[36] examined 127 cases of scarlet fever at the Boston City Hospital. He found that eighty-four of the cases had adenoids and forty-three of the cases did not have adenoids. Of the eighty-four cases with adenoids, twelve of them, or 14 per cent., had ear complications, while there were no aural complications among the forty-three cases that did not show the presence of adenoids.

In connection with nasal and nasopharyngeal abnormalities it should be emphasized that any factor that lowers the resisting power of the patient, or a functional derangement of other organs of the body, may be an important factor in causing or maintaining the diseased condition of the upper respiratory tract, which may be the cause of a middle-ear involvement. This is particularly true of granular pharyngitis, which is often due to gastro-intestinal disturbances.

From this brief consideration of the etiologic relationship between diseases of the nose and throat and diseases of the middle ear, I would emphasize the following points:

1. A very large proportion of people are subject to some aural defect; disease of the middle ear furnishes from 65 to 70 per cent. of all aural diseases, and of all cases of deafness the middle ear is responsible for about 85 per cent.

2. Of all sources of involvement of the middle ear, about 90 per cent. are caused by involvement through the Eustachian tube.

---

[29] Cobb: Med. Rec., New York, 1908, lxxiii, 818.
[30] Jackson: Brit. Med. Jour., 1907, ii, 969.
[31] Woakes: Quoted by Jackson, Brit. Med. Jour., 1907, ii, 969.
[32] Grant: Laryngoscope, January, 1907.

[34] Wyss: Quoted by Sendziak.
[35] Jurasz: Die Krankheiten der oberen Luftwege, 1891.
[36] Leland: Laryngoscope, October, 1909.

3. Adenoids in children are complicated by ear diseases in at least 30 per cent. of the cases. This percentage will be much higher if careful objective aural examinations are made and any change in the appearance of the drum membrane noted.

4. The nasopharynx is directly responsible for a very great majority of all diseases of the middle ear, and any intranasal or sinus disease that is capable of causing a nasopharyngitis, or is attended by a purulent discharge, or so interferes with drainage of the nasal passages that accumulated secretions may gain entrance to the Eustachian tubes, is a constant menace to the middle ear.

5. Many cases of chronic catarrhal otitis media that apparently begin in adult life, are the result of some diseased condition of the nasopharynx existing during childhood.

6. The presence of hypertrophy of the pharyngeal tonsil increases greatly the liability of serious middle ear complications during an attack of the acute exanthematous diseases.

7. Any conditions that interfere with the normal physiologic action of the Eustachian tubes will predispose to middle-ear disease, and the means of obtaining and maintaining such normal function of the tubes is through a normal nasopharynx and an important factor in maintaining a normal nasopharynx is a normal nose and fauces.

602 Nicollet Avenue.

WHAT IMPROVEMENT CAN RATIONALLY BE EXPECTED FROM TREATMENT OF THE NOSE AND THROAT IN MIDDLE-EAR DEAFNESS?*

JOHN F. BARNHILL, M.D.
Professor of Oto-Laryngology, Indiana University School of Medicine
INDIANAPOLIS

The title of this paper suggests that diseases of the nose and throat may cause, or at least may perpetuate when once begun, diseases of the ear. I believe no qualified aurist to-day questions the statement that pathologic states of the upper air tract exert a continued evil influence on the ear; and since the amount of benefit to hearing which may be derived from treatment of the nose and throat will depend largely on how much harm to the ear a given nasal or throat affection may have, or is continuing to exert, on the aural function, it will be necessary at the outset to discuss briefly two points, namely: (1) the dependence of normal aural function on a perfectly normal state of the nose and nasopharynx; (2) the determination of the manner in which a diseased aural environment may affect the middle ear; for, with the physiologic and clinical facts relating to these points before us the answer to the question involved in the title to this paper may be sufficiently answered in a few brief paragraphs.

Otologists are familiar with the fact that, in order to functionate normally, the drum-cavity must at all times contain air at a pressure approximating that which surrounds the body as a whole, and that which presses on the external surface of the drum-head in particular; that the normal air of the middle ear must be replenished by the circulation of air through the Eustachian tube; that such circulation of air in the drum-cavity, to the end that there shall be an equality of pressure on both sides of the membrana tympani, is brought about, not inevitably or by chance, but by the action of a delicate, well-balanced system of muscles, including the palatoglossei, the palatopharyngei and the palatolevatori.

Granting that the renewal of air in the middle ear is necessary to a healthy function, and that the coordinate action of the above system of muscles is essential to bring about the necessary renewal of air in the drum-cavity, it becomes easy to understand that the presence of any pathologic condition in the nose or nasopharynx which by mechanical pressure in any way hinders the action of this group of muscles, or which, because of adjacent disease and infection, may in any way impair their function, will, in proportion to the degree of such injury, impair the function of the middle ear and thereby open the way to aural diseases of a congestive, exudate or infective nature. Any hypertrophy, deformity or new growth in the posterior portion of the nose or of the nasopharynx constitutes such an obstruction. Take, for instance, one of the commoner affections which block the nose or nasopharynx, such, for example, as an adenoid hypertrophy, cystic polypus or posterior nasal hypertrophy. How do these affect the middle ear? In three ways: 1. The normal function of the entire epipharynx is mechanically interfered with. Normal action of the tubo-palatal muscles is hindered to an extent that the Eustachian tubes are not sufficiently opened for ventilation. Since nasal respiration is impossible, mouth breathing is enforced, and one physical result is that the air in the nasopharynx, Eustachian tubes and middle ear is thereby constantly exhausted and rarefied. This rarefaction is made more complete by the act of swallowing, which, when performed by persons whose nose or nasopharynx is obstructed from any cause, forcibly sucks the air from the tubes and middle ear, thus impairing function and inviting middle-ear disease. 2. The venous return circulation from the middle-ear and Eustachian tube empties into the veins of the pharynx. Local pressure, therefore, of obstructive growths in or near the nasopharynx retards this circulation to an extent that congestion of the mucous lining of the tubes and drum-cavities takes place, with the inevitable result that exudates or transudates into the middle ear sooner or later occur. Such a venous congestion must be regarded as a potent predisposing cause of suppurative otitis media as well as of the several plastic affections commonly known as dry middle-ear catarrh. 3. The mechanical stimulus produced by the presence of any growth in the nasopharynx results in the secretion of large quantities of ropy mucus, which, because of the difficulty with which it is dislodged by the patient, becomes stagnant and infected. This is especially true in case the obstruction is an adenoid hypertrophy. An examination of many hundred specimens of adenoid hypertrophy that were removed *en masse*, by one sweep of the adenoid curette, shows that this growth consists of several lobes which are separated by fissures which often extend from the surface of the adenoid down to the underlying fascia. In large adenoid hypertrophies these fissures are sometimes an inch long and almost half as deep. These deep recesses produce and harbor much of the vitiated, infected mucus in question. The adenoid itself is the seat of inflammatory action as a result of almost every sudden change of temperature. An examination of the nasopharynx of the adenoid patient shows, in nearly every instance, the presence of the vitiated mucus which covers the hypertrophy, fills the crypts and often stretches from the adenoid to the lip of the Eustachian tube, to the upper surface of the palate, or to other neighboring structure. As already stated it is difficult, because of the obstructed nostrils and the thick consistency of the mucus, for the patient to dislodge this secretion, and, lying stagnant in the epipharynx as it must, it furnishes an excellent pabulum for the propagation and growth of pathogenic bacteria, which lie, as it were, at the very threshold of entrance to the middle ear, ever ready to invade this organ, whenever, as is usually the case in the presence of conditions here enumerated, a fertile soil has been prepared in the mucous membrane which lines the Eustachian tubes and middle ear.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Several otologists of note have stated that from 60 to 75 per cent. of cases of defective hearing, with or without aural discharge, can be fairly attributed to the presence of an adenoid, either now or at the time of onset of the aural affection. I quite agree with Bryant in his statement that the cause of tubal entrance of infections is nearly always some nasopharyngeal disturbance which interferes with the normal drainage function of the Eustachian tube, and that 95 per cent. of all middle-ear suppuration is due primarily to the tubal entrance of bacteria, and secondarily to abnormal conditions in the nasopharynx which interfere with the expulsion of bacteria.

It is rare, in my experience, to find a child with well-developed adenoid, untreated till the age of 10, in whom there is not found an easily discoverable loss of hearing. Both parent and patient may and often do stoutly assert that the hearing is perfect, and are in many instances honestly mistaken in this belief; inasmuch as they base their opinion on the fact that the child continues to hear spoken words without apparent difficulty. Ability to hear spoken words fairly well is, as we all know, not a sufficient evidence that the individual's hearing is unimpaired, for it is the common experience of all to find, on careful test by instruments of precision, that the function is often greatly impaired without the patient's having the slightest knowledge of the fact.

Although adenoid hypertrophy stands first as the initial cause of middle-ear deafness, the ill effects on the ear are not limited to early childhood, or to that period of the patient's life in which the adenoid is usually largest. While an adenoid may remain large to the fortieth year, as I have witnessed, it usually atrophies to a greater or less degree before the twentieth year. In its atrophic state, however, it continues to exert its damaging effect on the ear, for it continues, especially in bad weather, in a thickened and much-inflamed state, and, moreover, the fissures which originally separated the lobes, continue into old age, furnishing a perpetual source of mucoid, infected secretion. In most of these cases of long-standing adenoid on thorough inspection of the whole nasopharynx by means of the rhinoscopic mirror or pharyngoscope, it will be found that there is present a chronic nasopharyngeal inflammation. In many cases adhesive bands are seen, stretching between the posterior lip of the Eustachian tube and a near-by lobe of the adenoid. In some instances there exists an inflammatory adhesion between one or more lobes of the adenoid, and in nearly every instance gross evidence of a damaged and unhealthy epipharynx is present.

It has been pointed out by Reik and others that the faucial tonsils are a potent factor in the causation of middle-ear affections; that when hypertrophied and diseased they cause impaired ventilation of the tympanic cavity because of mechanical interference with the tubo-palatal muscles; that they harbor infection in the tonsillar crypts and as a result of pressure-interference with the return venous circulation from the middle ear they cause passive congestion in the latter cavity. Both from a dissection of the parts involved, and from a study of the anatomic region, as shown in the drawings of the most eminent anatomists, I am unable to infer that the tonsils could, except when very greatly enlarged, interfere seriously with the normal action of the tubal muscles, or could by pressure greatly retard the venous circulation from the drum cavity; but when they are greatly hypertrophied both these evil results are, I think, clearly apparent. It is, however, true, without question, that the medium-sized, or even small, diseased and submerged faucial tonsil, is a constant menace to the middle ear because of the large amount of infectious substance it constantly retains in its crypts, and because of the acute and severe inflammatory states it so readily takes on, as in tonsillitis and quinsy.

Other new growths or hypertrophied structures, for example, such as nasopharyngeal fibroid, affect the function of the middle ear in the same manner as just described in cases of adenoid hypertrophy, the chief difference being that the adenoid, because of its deep and numerous fissures, furnishes a better field for the growth of pathogenic bacteria, whereas other hypertrophies are usually smoother and harder and do not, therefore, retain the infected, vitiated mucus so well. But no matter what the nature of the obstruction, the continued presence of any obstructive growth in the nasopharynx which interferes with the function of the upper air-tract, becomes a menace to the integrity of the ear. Indeed, clinical experience has amply demonstrated the fact that few patients escape serious damage to the ear provided the nose or nasopharynx remains obstructed for any considerable length of time.

With the above considerations of the intimate physiologic and pathologic relations of the nose and throat to the middle ear in mind, we may more intelligently proceed to answer the question, "What improvement can rationally be expected from treatment applied to the nose and throat in cases of middle-ear deafness?" The answer to the question has been so clearly anticipated by what I have already said in describing the absolute dependence of the health of the ear on a normal state of the nose and throat that it is now necessary to add but little more. I think that the reply can be best given by dividing all aural affections into three periods, and then stating the effect of throat and nasal treatment on the aural disease in each. Following this plan we have, (1) cases in that period of the child's life before any aural disease is actually present; (2) cases in the period when there is an easily discoverable aural ailment, but at a time before the aural structures are seriously or permanently damaged; (3) all cases that have reached the period of chronicity, in which marked and more or less permanent changes in the middle ear are easily discoverable.

In the first of the periods above mentioned the results of treatment of the nose and throat on the ear are entirely prophylactic, since no aural affection is present in the case, and, viewed in this light, may not fall strictly within the subject assigned me. The importance of such treatment at this time, however, furnishes ample justification for the brief paragraph I shall devote to it.

I have for some time entertained the belief that much of the deafness that exists to-day is entirely unnecessary, and that it could have been prevented if intelligent efforts had been made to do so at a time in the child's life before the actual aural affection began. It is the opinion of many otologists that disease of the middle ear seldom starts in the ear itself, but on the contrary has its beginning, almost without exception, in a diseased aural environment, and later extends to the ear from the latter place. Rational treatment of the affected aural environment at this early period, will, therefore, in the vast majority of cases, be the means of preventing subsequent middle-ear disease. By rational treatment I mean the complete removal by surgical means, of all obstruction to normal nasal respiration, and to nasal and aural drainage, at the earliest possible time after it is known that such nasal or nasopharyngeal disease is present.

Patients belonging to the second period suffer only from acute or subacute aural ailments which have been originally set up by impaired nasal respiration plus faulty drainage of the nose and nasopharynx, and which are kept active by continued action of these causes. My experience in dealing with this class is, that good and satisfactory results are obtained in proportion to our ability to eradicate the diseased aural environment. Good drainage from the tympanic cavity is just as essential to successful treatment of middle-ear disease as it is to the satisfactory management of any other infected cavity, and hence this well-known principle of surgery should be followed here as elsewhere, to the extent of providing and maintaining a natural open-air channel between the deeply seated mucous cavity of the ear and the larger air-space of the nasopharynx to which it is accessory. In this period of the progress of the aural affection no plan of treatment yields results that can be favorably compared to those obtained from well directed surgery of the nose and throat. Even in the suppurative aural affections, when destruction of aural tissue has not been great, good results, both as to preservation of hearing and arrest of aural discharge, are usually obtained in greatest measure through medical and surgical means directed toward the nose and throat, for through such means only may we expect successfully to eradicate the bacteria breeding-places, to provide a nomal ventilation to the tympanum and to restore the function of the tubopalatal muscles, all of which improvements to the aural environment are entirely essential, as already shown, to the preservation of aural function.

While it is true that the degree of hearing which may be preserved by this plan of treatment during this period of the aural disease may fall far short of the normal, nevertheless, as already stated, not every one knows the normal, and hence the ordinary patient is well satisfied when he is able to hear common conversation distinctly and to discharge social and business duties without embarrassment.

In the final stages of the middle-ear disease, when tissue changes are palpable and of long standing, the benefits to the ear to be derived from the treatment of the nose and throat become less and less until ultimately no relief whatever may be expected. And yet in some such cases which are well advanced Emerson of Boston has stated that nasopharyngeal treatment is sometimes helpful. Emerson has especially pointed out the good results which may be obtained from breaking up any adhesions that may be found between the posterior lip of the pharyngeal Eustachian tube and a near-by lobe of an atrophied adenoid. He has also found in some cases that the fossa of Rosenmüller was filled with granular adenoid structure, the removal of which has resulted in the improvement of an existing tinnitus and marked benefit to hearing. Logan has obtained equally good results to hearing from the eradication of old, inflamed, adherent adenoid pads, after first breaking them up by means of the finger and then by the employment of the curette or other convenient method of complete removal. While I have secured encouraging results from the employment of the above and other means of nasal and nasopharyngeal treatment in a small percentage of cases, it is my belief that we should expect little in the way of comfort or improvement to hearing in the vast majority of cases. Indeed the ratio between the length of time the aural affection has existed and the amount of benefit that may be expected from treatment of the environment of the middle ear is very direct.

Briefly, it may be said that the earlier nasal and nasopharyngeal treatment is instituted the better the result, and *vice versa.* The statement may be positively made that, when nasal and nasopharyngeal disease is eradicated before the onset of an ear disease in the individual, disease of the ear will usually be prevented. When the child is permitted to "outgrow" the aural ailment, only partially successful results are possible at any time. When the aural affection is allowed to become chronic the value to the ear of nasopharyngeal treatment becomes progressively less effective in proportion to the degree of chronicity. Stated differently, nearly all middle-ear diseases are preventable by early treatment of the diseased environment; most are satisfactorily helped by such treatment in the early stages of the aural involvement; few are benefited by such treatment in the chronic period.

ABSTRACT OF DISCUSSION

DR. F. P. EMERSON, Boston: I think we are all agreed, as the various writers have stated, that the majority of these cases of otitis media originate in the nasopharynx, with the possible exception of those due to trauma, some cases of virulent external otitis, those due to accumulation of cerumen (cases which may themselves be due secondarily to the infection of the nasopharynx), cases due to fracture of the base of the skull, to labyrinthine invasion from meningitis and possibly a few cases of infection from the blood-current. We may expect improvement to the extent that we can localize and drain the focal infection. Treatment, in the nasopharynx, consists in the relief of the infection, which is communicated to the middle ear through the Eustachian tube. The middle-ear trouble is made progressive by constant reinfection. Any operation which does not take into account the involved sinuses, which may later reinfect the Eustachian tube, is of little moment from the otologic point of view. Many of these cases are of sinus origin. As the result of a hyperplastic ethmoiditis, which may be due to a deflected septum, obstruction of the frontal duct and an involvement of the frontal sinuses, which may in turn infect the ethmoid or sphenoid secondarily. Occasionally the sinuses may be involved from the start, with a virulent infection, but that is, in my experience, unusual. The point I wish to bring out is the importance of the Eustachian tube in keeping up, in these progressive cases of otitis, a constant infection, so that we do not get the improvement in the hearing after operation that we would otherwise expect. We are impressed, in using the instrument which I referred to yesterday, with the excursion of the Eustachian tube, which with normal deglutition opens and closes very widely. We find in a great many cases of unilateral deafness with tinnitus that there is granulation tissue in the fossa of Rosenmüller and it is constantly subjected to reinfection. We find also bands in the fossa. In many cases there is a congested area that extends into the tube. About five-eighths of the open end of the tube can be looked into during swallowing. We can determine the condition of the lining membrane of the tube and make out congestion, hypertrophy and atrophy. Sometimes we find lymphoid tissue in the tube. In advanced cases of otitis media, it does not make so much difference what is done in the nares, the patients will continue losing their hearing year by year. The greatest satisfaction follows treating the tube directly and relieving the infection. A great many of them, especially in chronic catarrhal salpingitis, have a narrowing of the tube, which is frequently quite marked at the isthmus. Sometimes there is a suppurative inflammation. Auscultation does not give any clue as to whether the tube is constricted. I have frequently inflated with air and then have been able to pass only a No. 2 sound, and could not pass Nos. 3 or 4, which showed narrowing.

Dr. Fred Stauffer, Salt Lake City: I would like to call attention to the condition of too greatly relaxed tympanic membranes from too much blowing of the nose. Dr. Heath of London has written an excellent paper on this subject. It is more important than we would think unless we look for that condition. From the frequent blowing of the nose, the Eustachian tubes are forcibly inflated and we have partial paralysis of the tensor tympani muscles and too much looseness of the ossicles and tympanic membrane, so that the sound wave does not produce acute hearing. In those cases we get better hearing on the street cars or railroad trains where the loud noises put these parts on tension. The treatment consists not only in the removal of the obstruction in the nose, which causes it originally, but also the toning up of the tympanic membrane with stimulants, as is outlined by Dr. Heath.

Dr. W. R. Murray, Minneapolis: I would only emphasize the fact that in middle-ear disease the amount of improvement to be obtained by treatment is inversely proportional to the extent to which the disease process has extended. In the exudative stage improvement may be expected from treatment. When advanced adhesive processes have taken place within the tympanum the results of treatment are very discouraging. Our treatment should be preventive.

Dr. J. F. Barnhill, Indianapolis: I only want to emphasize what Dr. Murray has said, that the one time to treat middle-ear trouble is before you get the disease—by preventing it.

REFRACTION CHANGES IN DIABETES [*]

CASSIUS D. WESCOTT, M.D., and JOHN B. ELLIS, M.D.
CHICAGO

Since Horner first called attention to the subject and reported two cases to the Ophthalmologic Society of Zurich in 1873, a number of examples of sudden change in the refraction of glycosuric patients have appeared in the literature. The text-books have had little to say on the subject and what is to be found in the standard works is misleading.

The object of this paper is to call attention once more to the fact that the refraction not only may be increased in diabetes, but that it may be diminished; that both changes may occur in the same patient; and that the changes bear no necessary relation to the amount of sugar in the urine. As is well known, diabetes sometimes causes a true paralysis of accommodation, and in a number of cases of refraction change due to this disease there has been either a limited range, or a more or less definite paralysis. One author, at least, it seems to us, has confused a case of increased hyperopia with paralysis of accommodation. This case will be referred to later. Cases of increase in the refraction of the eye (increased myopia or diminished hyperopia) in glycosuria have been reported by Grimsdale, Appenzeller, Hirschberg, de Schweinitz, Neuberger, Groenouw, and others; but with these we have no present concern. The following cases from the literature, it seems to us, offer trustworthy evidence of diminished refraction due to diabetes:

Horner's[1] Case.—The patient was a woman, aged 55, who since August, 1870, had suffered with diabetes mellitus, passing an enormous quantity of urine, heavily loaded with sugar. She had been wearing no glasses, except for near work at night, when she used R. E. +0.75 Sph. L. E. +1.50 Sph. By the end of October her sight was failing and her glasses no longer were suitable. On November 19, she accepted, both eyes, +2.75 Sph. R. V. =5/5, L. V. =6/5; +1.50 Sph. was added for near. There was no intra-ocular lesion. As the diabetes improved the convex lenses no longer suited. Jan. 13, 1871, she accepted, both eyes, +0.75 Sph. Vision was the same as above noted, and the correction for presbyopia also the same (+1.50).

Risley's[2] Case 1.—The patient was a woman, aged 49, who had improved under treatment, and developed dimness of vision only after her symptoms of diabetes were largely relieved. Her old lenses (+2.75 Sph.) no longer served, and her vision was reduced to 1/5 in the right eye, and 1/4 of normal in the left eye; and there was no range of accommodation. With mydriatic, the following refraction was revealed:

R. E. +5.00 Sph. +1.25 Cyl. Ax. 75°, V. =6/6, L. E. +6.00 Sph. +0.75 Cyl. Ax. 105°, V. =6/6.

Ten days later her vision was again dim with glasses, and she accepted:

R. E. +3.00 Sph. +1.25 Cyl. Ax. 75°, V. =6/6, L. E. +3.50 Sph. +0.75 Cyl. Ax. 105°, V. =6/6, and accommodation was still absent.

Fifteen days later she accepted:

R. E. +1.25 Sph. +1.25 Cyl. Ax. 75°, V. =6/6, L. E. +1.50 Sph. +0.75 Cyl. Ax. 105°, V. =6/6.

Through several months of careful observation no further change was noted, though the patient steadily grew worse, with persistent glycosuria.

Risley's[2] Case 2.—The patient, a man of 74, had suffered with diabetes for at least six years, when he complained of dimness of vision. His refraction proved to be:

R. E. +1.50 Sph. +1.25 Cyl. Ax. 180°, V. =6/7.5, L. E. +1.25 Sph. +1.25 Cyl. Ax. 180°, V. =6/10.

From this time (August, 1896) until April, 1897, there was no change in the eyes. April 23, he complained of dimness of vision for distance and inability to read even large type with his reading lenses. His diabetes at this time was improved. He now accepted:

R. E. +2.50 Sph. +1.25 Cyl. Ax. 180°, V. =6/7.5, L. E. +2.50 Sph. +1.25 Cyl. Ax. 180°, V. =6/10.

May 20, he returned complaining that his vision was blurred with the distance lenses after a few days' use, and that he must hold his book too close in reading. He accepted his old glasses and had vision: R. E. 6/7.5?, L. E. 6/10.

Carpenter's[3] Case.—The patient, a woman aged 51, had consulted Carpenter six years before on account of presbyopia. She now complained of sudden inability to see clearly at a distance or to read with her near glasses. Her refraction, which had been a slight myopic astigmatism, was now hyperopic: R. E. +1.50 Sph. V. = 6/6, L. E. +2.50 Sph. V. =6/6. With +2.25 Sph. added she read Jaeger 1 at 30 cm. The urine had contained a large amount of sugar four weeks previously; and a reduction in the amount of sugar, under strict dieting, was coincident with the failing vision. There was no lesion of media or fundi. In three weeks, vision again blurred with glasses and she showed a myopia of 0.50 D.

Gallus'[4] Case.—The patient was a man of 51, who had had symptoms of diabetes for some time but had been under treatment only two weeks. He had been seeing well at a distance and wearing +2.00 spheres for reading. Recently his distant vision had failed and he saw better for distance with his reading lenses which no longer served their former purpose. His refraction, on March 28, 1905, was found to be:

R. E. +1.50 Sph. +0.50 Cyl. Ax. 180°, V. =5/8, L. E. +2.00 Sph. +0.50 Cyl. Ax. 180°, V. =5/5. +2.00 Sph. added enabled him to read the finest print. The eyes were in every way normal except for a slight pallor of the temporal halves of the disks and slight narrowing of the form fields with overlapping of red and green. May 23, the sugar was absent, and the patient was using his old correction (+2.00 Sph.) for reading. Refraction now was:

R. E. +0.50 Sph. +0.50 Cyl. Ax. 180°, V. =5/7, L. E. +0.50 Cyl. Ax. 180°, V. =5/5. With +2.00 Sph. added for near he was able to read the finest print. The fields were now noted as being wider but not normal.

LICHTENSTEIN'S[5] CASE.—This is of especial interest, inasmuch as it exhibits diabetes in a youth of 17 years, with complete paralysis of accommodation and an increase in hyperopia, proved by repeated examinations under cycloplegia. This patient showed, on March 8, 1906, a slight anisocoria, and reduced vision. His eyes were otherwise normal. His manifest refraction was +1.50 Sph., both eyes, V. =6/6. This agreed with retinoscopy. A +12.00 Sph., both eyes, was required to read Jaeger 1 at 9 cm. The diagnosis of complete double-sided paralysis of accommodation was made, for which no cause could be discovered by the ophthalmologist or neurologist, except diabetes, which was established by the internist. There was 4.5 per cent. of sugar in the urine, of which six liters were passed daily. The diabetes increased in spite of treatment. On the following day the manifest refraction was +2.50 Sph., and +13.00 Sph. was required for near. Homatropin was then used, with the same finding; namely, +2.50 Sph. Two days later, under atropin cycloplegia, hyperopia =3.50. There was no change in the next two weeks, during which time the sugar was reduced and the patient gained in weight. In another week the refraction was still +3.50 Sph., and now a +11.00 Sph. was sufficient, instead of +13.00, to bring the near point to 9 cm. Thereafter a steady strengthening of the accommodation was manifested by the progressively smaller convex lenses required, until two months later, when a +5.00 Sph. sufficed. During this time the hyperopia was found to be 3.00, 2.50, 2.00, and finally 1.50, the latter estimate being with atropin cycloplegia. The thoroughness of the use of cycloplegia in this case is attested by the patient's refusing to return for further examination on account of his fear of atropin.

LANDOLT'S[6] CASE.—No mention is made of the use of a cycloplegic, and the amount of hyperopia developed is too small to be conclusive. The patient was a woman, the subject of a traumatic diabetes, who had arrived at an age when the accommodation is almost *nil*, and in whom the refraction was made repeatedly with great care, according to the authors' statement. A hyperopia of 0.50 developed, and the refraction showed variations in direct proportion to the amount of sugar in the urine, finally returning to emmetropia.

DOYNE'S CASE.—Unfortunately we do not know the refraction of Doyne's[7] patient, a physician aged 40, previous to his acute diabetes; but the subsequent history points strongly to an increase of hyperopia, later approximating emmetropia with the cure of the diabetes. Early in the course of the disease, when vision had become very dim, hyperopia was 3.00 D. With improvement in the patient's general condition the error gradually lessened until, when the urine was entirely free from sugar, the refraction was +0.75 Sph. with homatropin cycloplegia.

JACKSON'S[8] CASE.—A woman, aged 52, came with a history of diabetes of some years' standing. Recently the amount of sugar had greatly increased and the general condition was worse. Until a few weeks before, the patient's distant vision had been good. At the time of her visit vision was 4/60. With R. and L. +2.25 Sph., vision was 4/4. These lenses were prescribed for distance, and +2.00 added for near. Three months later she returned complaining that she could not see with the distance glasses and the reading lenses were unsatisfactory. Vision without lenses was now 4/4, and the same with +0.50 Sph. She was given +2.75 Sph. for near work and there was no change six weeks later, but she grew rapidly worse and soon died.

LUNDSGAARD'S[9] CASE 1.—The patient was a woman of 57, who was given +0.50 Sph., both eyes, V. =6/6, in March, 1902. No lesion was found in her eyes at this time. In July, 1905, she developed abnormal thirst and hunger and passed three to four liters of urine daily. Numerous examinations of the urine during 1905 revealed no sugar. A trace was present in February, 1906. In August, 1906, there was 7.75 per cent. of sugar. With restricted diet the percentage fell to 2.25 per cent. in ten days. August 24, the patient noted a dimness of vision which remained unchanged for eight days. Examination revealed R. E. +2.50 Sph. V. =6/6; L. E. +2.00 Sph. V. =6/6. No lesion of either eye. Accommodation was recorded as corresponding to the patient's age. The sugar diminished in quantity during September, and on September 15 the refraction was: R. E. +2.00 Sph., L. E. +1.50 Sph. By October 14 sugar was absent, and on November 19 the cloudy vision had disappeared. She read with her old reading lenses, and the refraction was the same as in 1902 (hyperopia =0.50), with normal vision.

LUNDSGAARD'S[10] CASE 2.—The patient was a woman aged 50. She had had diabetes for half a year. July 8, 1907, she suddenly found that her glasses (+1.50 Sph.) caused blurring. Her refraction was now found to be R. E. +3.00 Sph. V. =6/6, L. E. +3.50 Sph. V. =6/6. Accommodation was normal and ophthalmoscopic findings normal. Tension normal. Two days later the dimness of vision vanished and she saw with her old glasses. On July 15, the refraction was recorded as emmetropic. V. =6/6. The sugar, which was 6.2 per cent. on June 26, fell to 2.5 per cent. on June 29, 1.7 per cent. on July 2, 0.3 per cent. on July 5, 0.2 per cent. on July 8; thus we note a sudden increase in hyperopia occurring some days after the sugar had fallen from a high percentage to a mere trace. The accommodation remained normal throughout. The author states that he had no opportunity to use atropin.

LUNDSGAARD'S[10] CASE 3.—This is unique in the thoroughness with which it has been studied and reported. A woman, aged 50, stated that her vision had been good until presbyopic symptoms appeared one year previously. She had been given a glass for near work which was later increased to +1.50 Sph. For a half year she had suffered with diabetes, and the sugar had increased from 2.5 per cent. to 6 per cent. At the time of her first visit (Nov. 5, 1909) she was disturbed by blurring of distant vision and inability to use her reading lenses. She had headache and saw objects distorted, curved and angular, with the left eye. Refraction showed R. E. +1.50 Sph. V. =6/6, L. E. +2.00 Sph. V. =6/12. With +3.50 Sph. both eyes, she could read Jaeger 1. With the left eye the letters were out of line, some higher, some lower. The Schiötz tonometer revealed normal tension and the Javal ophthalmometer showed corneal astigmatism. The right pupil was slightly smaller than the left. Both reacted normally. The media were clear except for a mass of grayish, punctate flecks, partly vacuoles, in the right eye. They appeared to be in the front part of the lens, distinctly seen with the corneal loupe. The left eye showed no such appearance when the pupil was widely dilated with homatropin.

November 15, R. E. +2.50 Sph. V. =6/6—; L. E. +2.50 Sph. V. =6/12.

November 18, sugar 0.85 per cent.

November 22, no change; atropin, left eye.

November 30, R. E. +1.00 to +1.50 Sph. V. =6/6—; L. E. +2.00 Sph. V. =6/12.

November 15, R. E. +2.50 Sph. V. =6/6—; L. E. +2.50 Sph. V. =6/12—.

December 30, refraction and vision were unchanged. Flecks and vacuoles unchanged. Sugar 2.3 per cent.

January 16, 1910, no change in refraction or vision. Atropin was used each time in the left eye in order to study the lens changes with a dilated pupil. The opacities seemed less numerous than formerly and very superficial and mostly in the periphery.

February 1, the right eye was reported emmetropic with vision 6/9; the left eye (manifest and under atropin) +0.50 Sph. V. =6/12. The distortion of objects in the left eye was unchanged, though the usual tests with straight lines for metamorphopsia showed no abnormality. During these numerous examinations, the ophthalmometer and tonometer readings showed at no time any change in tension or corneal astigmatism. The patient said that she saw as well as before the development of her diabetes, though the lens opacities remained unchanged.

KNAPP'S[11] CASE 1.—The patient was a woman of 47, who was found to be emmetropic by skiascopy, and accepted no

lens for distance, in December, 1907. She was given +1.25 Sph. for her presbyopia. Oct. 26, 1908, she reported that she had suffered with diabetes since the first of the year, and for several days her vision had been poor for distant and near objects. Her vision was 6/36. Skiascopy showed hyperopia of 2.00 D., and +2.00 Sph. gave 6/9 vision. With +4.00 Sph. she read finest type at 30 cm. Ophthalmoscopy revealed red disks, but no lesion. November 9, there was no sugar in the urine and she accepted: R. E. +1.00 Sph. V. =6/6; L. E. +0.50 Sph. V. =6/6; agreeing with skiascopy.

November 23, R. E. +0.50 Sph.; L. E. +0.25 Sph. No sugar.

February 13, 1909, R. E. +0.50 Sph. V. =6/6; L. E. emmetropia, V. 6/6. R. E. +1.00 Sph. gives Jaeger 1 at 25 cm. L. E. +1.00 Sph. gives Jaeger 1 at 22 cm. The refraction was the same at this time with homatropin cycloplegia.

KNAPP'S[11] CASE 2.—The patient was a man of 48, who had a severe diabetes of only a few weeks' duration when, in April, 1908, he complained of dimness of vision, coming on over night, for both far and near. Skiascopy revealed a hyperopia of 1 D., and +1.25 Sph. brought vision up from 1/3 to normal. To read Jaeger 1 at 20 cm., +5.00 Sph. was required, showing a weakened accommodation. Four weeks later the sugar had disappeared and the patient's sight was good without lenses. Skiascopy revealed emmetropia and V. =6/6 without lenses. Accommodation, 2 to 2.50 D. In March, 1909, *emmetropia, both eyes, and V. =6/6. With +1.00 Sph. the* patient read Jaeger 1 at 35 cm. He continued well and worked as a chemist without glasses. Neither of Knapp's cases had any abnormality of tension or demonstrable lesion in the eye.

ZENTMAYER'S[12] CASE.—The patient was a woman, aged 58, who had been under treatment for glycosuria for three weeks when she consulted the ophthalmologist, Oct. 4, 1909, complaining of rapid loss of vision for the past ten days. She had worn glasses only for near work during the preceding six years, but now could see better with these lenses for distance than without them. Vision was R. E.=6/60, L. E.=6/60; fields practically normal. Tension of left eye +?. There was marked arteriosclerosis of the retinal vessels. Otherwise the eyes were normal. Refraction was found to be:

R. E. +2.50 Sph. +0.25 Cyl. Ax. 165°, V. =5/5, L. E. +2.50 Sph. +0.50 Cyl. Ax. 15°, V. =5/5; +2.50 Sph. added, both eyes, enabled her to read type 0.37 at 25 cm. October 26, there was no change noted in the hyperopia or vision. November 9, R. E. +1.25 Sph. V. =6/5 pt.; L. E. +1.25 Sph. V. =6/5 pt. Accommodation unchanged.

Jan. 17, 1910, R. E. +0.50 Sph. V. =6/6 pt.; L. E. +0.75 Sph. V. =6/6 pt. Accommodation unchanged. Dr. Zentmayer states that the sugar, which had been as high as 5 per cent., was lessening at the time when vision failed, and had been absent for two days previous to her first visit to him (October 4).

ROBERTS'[13] CASE.—Roberts reported the following case under *the title of "Transient Cycloplegia Due to Glycosuria"*: A man, aged 51, the subject of diabetes, complained of inability to read with his old reading lenses and inability to see distant objects distinctly without lenses. Heretofore he had seen distinctly, without lenses for distance, and with +1.75 Sph., both eyes, for near. The sugar in the urine was now 3/8 per cent., whereas two weeks before it had been 7 per cent. R. E. V. =6/22.5; L. E. V. =6/15. Manifest refraction was: R. E. +1.75 Sph. V. =6/5; L. E. +1.75 Sph. V. =6/5. The addition of +2.25 Sph., both eyes, was necessary to bring the near point to 13 inches. No lesion was discovered in either eye. One month later his general health was improved. His last glasses had been satisfactory until within a few days; but now they blurred his distant vision, and required that he hold his book too close to the eyes. Vision, with correction, was 6/12. Manifest refraction showed: R. E. +1.00 Sph. V. = 6/5; L. E. +0.75 Sph. V. =6/5; with +2.25 Sph. added for near. Nine months later he reported that his eyes had gradually returned to their previous condition and he used his original lenses for reading (+1.75). It would seem to us that this is really a case of increase of hyperopia in the course of diabetes, with a very small amount of paresis of accommodation; for the patient required +1.75 Sph. for presbyopia before his diabetes, and only +2.25 Sph. added to his distance correction when first seen by Dr. Roberts; and when seen later his presbyopia remained the same, while his hyperopia had diminished 0.75 D. in the right eye and 1.00 D. in the left; later still both the hyperopia and the slight paresis of accommodation disappeared practically, allowing the use of the original reading lenses only (+1.75).

GOULD'S[14] CASE.—In April, 1907, Dr. George M. Gould reported a case of rapidly changing refraction in the person of a physician suffering from glycosuria, and reviewed the literature. His patient was a man, 58 years of age, whose eyes he had repeatedly examined under cycloplegia. In December, 1902, he had been wearing:

R. E. —2.62 Sph. —0.75 Cyl. Ax. 35°, V. =20/20+; L. E. —2.62 Sph. —1.25 Cyl. Ax. 167°, V. =20/20+, with +1.75 added for near in bifocals. On the eighteenth of that month the patient complained of eye-strain and blurred distant vision and accepted the following:

R. E. —3.25 Sph. —0.75 Cyl. Ax. 25°, V. =20/20+; L. E. —3.25 Sph. —1.50 Cyl. Ax. 166°, V. =20/20+, with +2.12 added for near in bifocals. There was also a limitation of the range of accommodation. Other symptoms suggested examination of the urine, which was found loaded with sugar. A strict diet was prescribed, *and in a week the sugar had disappeared* from the urine, but the eye-strain had returned. A reexamination showed that the error of refraction had returned almost exactly to the point of seven days before. In the next four years the patient was less careful of his diet, and in December, 1906, accepted the following:

R. E. —2.87 Sph. —0.37 Cyl. Ax. 25°, V. =20/20+; L. E. —3.00 *Sph. —1.50 Cyl. Ax. 172°, V. =20/20+, with +2.50* added for near in bifocals. In February, 1907, there was increasing evidence of ill health, a high percentage of sugar in the urine, and symptoms of eye-strain. The rigid diet was resumed and in a few days the glycosuria had disappeared, but the eye-strain was worse than ever. Examination showed the following error:

R. E. —2.00 Sph. —0.62 Cyl. Ax. 20°, V. =20/20+; L. E. —1.87 Sph. —1.37 Cyl. Ax. 170°, V. =20/20+, with +2.00 added for near.

Dr. Gould writes us that the patient continues in good health and is now wearing:

R. E. —2.50 Sph. —0.87 Cyl. Ax. 35°, V. =20/20+; L. E. —2.50 Sph. —1.50 Cyl. Ax. 170°, V. =20/20+, with +2.37 added for near.

Attention is called to the fact that, ignoring the astigmatism, the myopia increased from —2.62 to —3.25 and then, after a period of careful dieting, fell to —2.00 in one eye, and —1.87 in the other, five-eighths of a diopter in one eye and three-quarters in the other, below what may be termed the normal myopia for the individual—the amount present before the glycosuric changes began. This, we believe, is not to be explained on the ground of careless refraction or lack of cycloplegia.

Dr. Gould very properly calls attention to the fact that no case of this sort can adequately be studied without cycloplegia if the patient still retains any accommodation, and that the previous static refraction should be known. He also says that there is no reported case of myopia (with sudden change in diabetes) in which glycosuria has not had the effect of increasing the myopia. He believes it illogical, if not impossible, that the same cause can also bring about an increase of hyperopia, and questions the accuracy of the observation of those who have reported such cases. It seems to us that Dr. Gould's own case disproves his contention. As we have already pointed out, after increasing and then falling back to normal, and increasing again, his patient's myopia diminished five-eighths and three-quarters of a diopter below the starting point. The following cases from our practice, however, show that the refraction may increase and diminish in the same patient in glycosuria:

[14] Gould: New York Med. Rec., April 20, 1907.

Wescott's Case.—Miss K. H., stenographer, aged 36, was referred to one of us (C. D. W.), because of headache, in February, 1896. Under complete cycloplegia with homatropin and cocain she accepted:

R. E. +0.75 Sph. V. =6/6; L. E. +0.75 Sph. V. =6/6. She was given the full correction for near work only, with relief from her headaches. In May, 1898, she was complaining again and under homatropin and cocain accepted:

R. E. +0.87 Sph. V. =6/6; L. E. +0.62 Sph. V. =6/6. She was given the above, less 0.25 Sph., for constant use, and was again relieved of her symptoms. In May, 1903, she suffered again from headache and was again examined under homatropin and cocain, accepting:

R. E. +1.00 Sph. +0.25 Cyl. Ax. 180°, V. =6/6+; L. E. +1.25 Sph. +0.25 Cyl. Ax. 180°, V. =6/6+. She was given the above, less 0.37 Sph., and was comfortable once more. In July, 1906, she was again complaining, and under the same cycloplegia accepted:

R. E. +1.25 Sph. +0.25 Cyl. Ax. 180°, V. =6/6; L. E. +1.00 Sph. +0.25 Cyl. Ax. 180°, V. =6/6. Given the above, less 0.25, for distance and added +0.50 for near in bifocals. In September, 1907, when the patient was 47 years of age, she returned, saying that she could not see well with her distance glasses. The external eye, reflexes, and fundus were normal. Under homatropin and cocain she now accepted:

R. E. —0.25 Sph. +0.50 Cyl. Ax. 15°, V. =6/6—; L. E. —0.25 Sph. +0.50 Cyl. Ax. 165°, V. =6/6—. A few days later without cycloplegia she accepted:

R. E. —0.50 Cyl. Ax. 105°, V. =6/6—; L. E. —0.50 Cyl. Ax. 75°, V. =6/6—. This was prescribed, with +0.75 Sph. added in bifocals. There was no paralysis of accommodation. Diabetes was suspected and the patient was advised to consult her physician for general examination and treatment. November 2, 1907, she returned, complaining that she could no longer see to read with the glasses prescribed in September, and her bifocal segments were increased to +1.50 Sph. At this time her physician, Dr. Annie Sage, reported 5 per cent. of sugar in the urine. November 12, sugar 8.266 per cent. Acetone absent. March 19, 1907, the patient returned, complaining that she could not see well, far or near, with or without glasses. Examination showed that distant vision was reduced to 6/45, with either eye, with her correction, and near vision to Snellen 2 D. at 14 inches. With +3.00 Sph. added, distant vision was restored to 6/6—, and near vision to Snellen 0.50 D. at 8 to 18 inches. She was given +3.00 Sph. in a grab front to be worn over her bifocals. Sugar 4.533 per cent. Diacetic acid and acetone absent.

November 25, sugar 6 per cent.

December 2, sugar 4.266 per cent.

December 12, 1907, the patient returned her grab front, as the vision had improved so much that she was able to get along with her correction. Distant vision at this time was 6/12 with either eye. There was 5.866 per cent. of sugar in the urine on March 28, 1908; she saw better without her glasses than with them, and was again examined under homatropin and cocain, with the following result:

R. E. +1.00 Sph. +0.37 Cyl. Ax. 180°, V. =6/6; L. E. +1.00 Sph. +0.37 Cyl. Ax. 5°, V. =6/6. The patient was given the above, less 0.25 Sph., for distance, with +1.25 Sph. added in bifocals. At this time when the refraction had increased to and beyond what was normal for her when the rapid change began, the urine contained 6.66 per cent. of sugar. After this examination, however, her health failed rapidly, the amount of sugar increased to 15 per cent., and she died in coma, without being seen by us again. This case also shows that hyperopia may decrease, increase, and decrease again, while the amount of sugar more or less steadily increases.

Ellis' Case 1.—Catherine M., domestic, aged 40, seen in December, 1907, for some time had noticed that vision was variable, and three weeks previously Dr. N. S. Davis of Chicago had diagnosed diabetes. Vision: R. E. 6/30; L. E. 6/15. Under cycloplegia with homatropin and cocain she accepted the following:

R. E. +4.50 Sph. V. =6/6+; L. E. +4.50 Sph. V. =6/6+. A few days later, without cycloplegia, she accepted:

R. E. +4.00 Sph. V. =6/6+; L. E. +3.75 Sph. V. =6/6+, and this was ordered for constant use. At this time the urine contained 3 per cent. of sugar.

In March, 1908, the patient returned, complaining that she could no longer see well with the glasses and had discarded them. Reexamination under homatropin and cocain gave the following result:

R. E. +2.25 Sph. +0.25 Cyl. Ax. 10°; V: =6/6; L. E. +1.57 Sph. +0.37 Cyl. Ax. 30°, V. =6/6. Given the above, less +0.50 Sph. The patient was then passing four quarts of urine containing 2.5 per cent. of sugar.

Ellis' Case 2.—Mrs. J. T. W., aged 48, was referred by Dr. Julius Hoelscher of Chicago in September, 1910. The patient complained that her eyes had so changed in the past few weeks that she could see clearly in the distance with glasses used for some time for reading, and that they were no longer satisfactory for near work. Dr. Hoelscher reported polydipsia and polyuria and 4.5 per cent. of sugar in the urine. No diacetic acid or acetone was present. The patient had been examined by him one year before, and six months before, and no diabetes was found. The external eye, the reflexes, and the fundus were normal. R. V. =6/45, L. V. =6/45. With old reading glasses:

R. E. +2.50 Sph. +0.75 Cyl. Ax. 45°, V. =6/5; L. E. +3.00 Sph. V. =6/5. Under homatropin and cocain the patient accepted:

R. E. +2.75 Sph. +0.50 Cyl. Ax. 60°, V. =6/5; L. E. +2.75 Sph. V. =6/5. After passage of mydriatic a few days later she accepted:

R. E. +2.50 Sph. V. =6/5; L. E. +2.50 Sph. V. =6/5. The above was ordered, with +1.50 Sph. added for near. There was no paralysis of accommodation. In December, 1910, the patient came complaining of poor distant vision with glasses, and stated that vision was much better without them. Examination showed vision 6/9 in either eye without glasses, and 6/30 with correction. Without mydriatic she accepted:

R. E. +0.75 Sph. +0.50 Cyl. Ax. 45°, V. =6/5—; L. E. +0.75 Sph. V. =6/5, which was given, with +1.50 added for near. At this time the urine was free from sugar. February 14, 1911, this patient was again examined under homatropin and cocain. The fundus was normal and she accepted:

R. E. +1.00 Sph. +0.37 Cyl. Ax. 45°, V. =6/6+3; L. E. +1.25 Sph. +0.25 Cyl. Ax. 165°, V. =6/6+4. A few days later without mydriatic she accepted the above, less 0.25, and +1.50 added for near. No paralysis of accommodation. This case, like our first one, shows an increase of hyperopia, though we do not know how much, followed by a very marked decrease.

Ellis' Case 3.—A woman, aged 65, was seen July 12, 1910, Her distant vision had been failing rapidly for three months, with dull headache on near work. The ophthalmoscope showed sclerosis of the lenses and pronounced retinal arteriosclerosis. R. V. =6/22—1, L. V. =6/22—1. She was wearing +2.75 Sph., both eyes, for near, and read Snellen 0.50 at 9 inches. Under homatropin and cocain she accepted:

R. E. —0.75 Sph. —1.00 Cyl. Ax. 15°, V. =6/9; L. E. —0.75 Sph. —0.50 Cyl. Ax. 135°, V. =6/12. She was given the above, with +2.50 added for near. On August 16, 1910, she saw better without glasses. R. E. V. =6/22; L. E. V. =6/22; with glasses V. R. E. =6/45; L. E. =3/45. Under homatropin and cocain she accepted:

R. E. +1.75 Sph. +0.25 Cyl. Ax. 120°, V. =6/9+; L. E. +1.75 Sph. +0.25 Cyl. Ax. 180°, V. =6/9. March 17, 1911, she again saw better without distance glasses than with them. She admitted carelessness in diet.

R. V. =6/12+, with correction =6/30; L. V. =6/12+, with correction =6/30. Under homatropin and cocain she accepted:

R. E. +0.75 Cyl. Ax. 130°, V. =6/9+2; L. E. +0.50 Cyl. Ax. 15°, V. =6/9—2.

A review of the above cases shows that a much more extended and accurate study is necessary for a solution of the problem involved. As has been pointed out, the static refraction of the patient in health should be known, and careful examinations are desirable as often, at least, as the patient is able to recognize changes in his vision. It goes without saying that all examinations should be made under cycloplegia when any accommodation remains which could interfere with accuracy. Frequent and regular examinations of the urine should be made for sugar and other substances which may affect the refraction or the accommodation. The fact that there is no definite relation between the amount of sugar in the urine and the refraction changes is very suggestive, as is also the fact that partial or complete paralysis of accommodation may or may not be present in cases showing an equal amount of sugar in the urine. The fact that the most startling changes in the vision and refraction have occurred when the general condition was improving and the urine free from sugar, points to the possibility of another agent as the offending factor in at least a portion of the cases. We regret exceedingly not being able to make more extended studies in our own cases; but two of our patients were working women who could give us little time, and who gave the internist even less opportunity for the study of their metabolism.

Numerous theories have been proposed in explanation of refraction changes in the course of diabetes, generally assuming that the presence of sugar in the lymphatic circulation of the eye produces alteration in the refractive indices of the media, cornea, aqueous, lens, and vitreous; or else that the volume of the globe is altered through the loss of fluid in diabetes. For example, Landolt[6] explained his case of diminished refraction on the theory of augmentation of the index of refraction of the vitreous body, since the vitreous presents a concave surface to incident rays. He thought that changes in the volume of the globe could not occur rapidly enough to account for the changes in refraction observed in his patient. On the contrary, Horner[1] believed that sudden loss of fluid from the eye was responsible for developing hyperopia. Schmidt-Rimpler,[15] not referring to diabetic cases especially, said that loss of fluid, with minus tension, does not alter the refraction of an eye. In perhaps the most thoroughly studied of all the cases found in the literature, Lundsgaard's third case,[10] repeated examinations with the ophthalmometer and the Schiötz tonometer revealed no alterations in corneal curvature or tension of the eyes during the period of varying refraction.

An increase of refraction in the course of cataract development is a very frequent phenomenon. On the contrary, Machek[16] detailed three cases of diminished refraction in the course of the development of subcapsular cataract with central transparency of the lens; and Priestley Smith[17] speaks of hyperopia developing in incipient cataract. In diabetic cataracts, the lens has been found, on chemical examination, to contain sugar (Liebreich, Leber); Nagel, on the contrary, did not find sugar in the lens. Lichtenstein[5] thought that change in the index of refraction of the lens was the explanation of his case, as did Knapp,[11] who compared the diabetic toxin with nicotin and strychnin in the rapidity of its action.

Against the idea of alteration in the refractive index of the aqueous caused by the presence of sugar in this fluid, is the experiment of Hess[18] showing that 20 per cent. of grape-sugar is necessary to produce a myopia of 1 D., while Deutschmann[18] noted cloudiness and swelling of a lens after immersing it in a 5 per cent. sugar solution for a few hours. Obviously these two experiments are inconsistent with the idea that a considerable change in refraction, without cataract formation, is due to the presence of sugar in the fluid bathing the lens.

It seems to us that none of these theories will do. The problem is an interesting one, however, and no doubt will some day be solved. It offers opportunity for the internist, the physicist, and the physiologic chemist, as well as the ophthalmologist.

In conclusion, we wish to express our indebtedness to Dr. Emory Hill for his painstaking care in abstracting the published cases, and for other assistance in the preparation of this paper.

31 Washington Street.

ABSTRACT OF DISCUSSION

Dr. William Zentmayer, Philadelphia: Dr. Wescott's analysis of cases is particularly interesting, especially those that have a decrease in the static refraction. The cause is difficult to explain. There are other known ocular changes in diabetes which may throw light on the cause of the decrease in refraction in this affection. We know that we have paralysis of accommodation, cataract and myopia as the result of diabetes. Now as to the accommodation theory, Dr. Roberts' case certainly indicates that a paresis of accommodation may be the cause of the decrease in the static refraction, but there are many cases on record in which the static refraction was known before the change took place, particularly in Risley's, Carpenter's and Lundsgaard's cases, and it was again estimated under atropin, and after the atropin had passed off and it was shown that it was due to actual change in the static refraction. In my own case I did not know what the static refraction was before, but during the time there was no change in the accommodation. Recently the patient has had a second attack and again there was no paresis of accommodation. Paralyses of accommodation in other affections are not so fugacious; they are not so intermittent as these changes which occur in diabetes. Then again, there is no other way of explaining the increase in refraction except by the swelling of the lens. I think it is fair to infer that the change, as curious as it is, must be a lenticular one. Now a possible explanation of it has been given by Grimsdale. If there is an increase in the index of refraction of the cortical layers of the lens there is a more uniform index in the entire lens, and such a lens, of course, is less refracting than a lens which has a different index of refraction in its various layers. It seems to me that this is a plausible explanation of these cases.

Dr. C. D. Wescott, Chicago: I am indebted to Dr. Zentmayer for his interesting remarks. As Dr. Roberts is not able to be here and was expecting to say something with reference to his own case, I should like to call attention to one or two points, and I will read my excerpt of his case. It was reported under the title "Transient Cycloplegia Due to Glycosuria:"

A man, aged 51, the subject of diabetes, complained of inability to read with his old reading lenses and inability to see distant objects distinctly without lenses. Heretofore he had seen distinctly, without lenses for distance, and with +1.75 Sph., both eyes, for near. The sugar in the urine was now 3/8 per cent., whereas two weeks before it had been 7 per cent. R. E. V. =6/22.5; L. E. V. =6/15. Manifest refraction was: R. E. +1.75 Sph. V. =6/5; L. E. +1.75 Sph. V. =6/5. The addition of +2.25 Sph., both eyes, was necessary to bring the near point to 13 inches. No lesion was discovered in either eye. One month later his general health was improved. His last glasses had been satisfactory until within a few days, but now they blurred his distant vision and required that he hold his book too close to the eyes. Vision, with correction, was 6/12. Manifest refraction showed: R. E. +1.00 Sph. V. =6/5; L. E. +0.75 Sph. V. =6/5; with +2.25 Sph. added for near. Nine months later he reported that his eyes had gradually returned to their previous condition and he used his original lenses for reading (+1.75). It would seem to us that this is really a case of increase of hyperopia in the course of diabetes, with a very small amount of paresis of accommodation; for the patient required +1.75 Sph. for presbyopia before his diabetes, and only +2.25 Sph. added to his distance correction when first seen by Dr. Roberts; and when seen later his presbyopia remained the same, whi [illegible] had diminished 0.75 D. in the right eye and 1.00 I [illegible] th the hyperopia and the slight paresis of [illegible] prac-tically, allowing the use of the origi [illegible] 1.75).

[16] Ztschr. f. Augenh., xix, 330.

[17] Smith, Priestley: Graefe-Saemisch Handbuch des gesamten Augenheilkunde, 11, vi.

[18] Hess: Quoted by Parsons: The Pathology of the Eye, iii, 929.

I venture to say that if Dr. Roberts had examined his patient under complete cycloplegia he would have no doubt in his mind as to my view of the case; for it then would have been most evident that there was a positive decrease in the refraction of the eye, with possibly a slight paresis of accommodation, followed by a return to the original condition with improvement in the patient's health.

Since coming to Los Angeles, I have been advised by telegram that Dr. Ellis has just seen an additional case of diabetes in a woman aged 40, with a sudden increase of hyperopia. The patient had been wearing +0.50 Sph. for distance, and +2.50 for reading. One week ago these lenses gave satisfactory vision. She now requires +2.00 Sph. with +0.50 Cyl. Axis horizontal for distance. Vision is 6/7, and accommodation normal for her age.

THE IMPORTANCE OF A CERTIFIED OR PASTEURIZED BUTTER *

ALFRED F. HESS, M.D.
NEW YORK

The title of my paper may seem somewhat out of the province of the activities of the Association of Certified Milk Commissions. However, the association has accomplished such laudable results in raising the standard of our milk-supply that it seemed only fitting that we should turn to it, in seeking a similar uplift of the standard of butter. It is indeed strange that in spite of our knowledge, the fruit of various investigations in this field, the attempts to provide a safe butter have been so feeble.

There is no need of repeating the evidence to the effect that cream contains tubercle bacilli even in larger amounts than the milk from which it is made. When the cream rises, whether it ascends by means of gravity or through the agency of centrifugal force, the fat globules carry with them a large proportion of the bacilli, which are filtered out from the underlying skim-milk into the cream and the sediment. The tubercle bacilli of the cream constitute the tubercle bacilli in the butter. It is difficult to state the percentage of contamination of the butter sold in large cities, but we probably shall not go far wide of the mark if we accept Cornet's[1] figure of 12 per cent. as an average. It has been demonstrated by Schroeder that these bacilli can maintain their virulence, in spite of the salt which the butter contains, for a period of three months. These facts naturally lead to a consideration of the subject which has been the main field of contention among those actively interested in the investigation of the cause of tuberculosis, namely, the importance of infection in man by the bovine type of tubercle bacillus, and of the alimentary tract as a portal of entry. It is not necessary in this place to discuss this question in detail. However opinions may vary on these questions, I think that almost all are now ready to accept the conclusion that the bovine bacillus constitutes a real menace to the welfare of infants and young children. The investigation in England by the British commission, the more comprehensive one in the United States by Park and Krumwiede, and that of the imperial Health Bureau of Germany force this deduction on us. So that it seems certain that in childhood, and especially in the first few years of life, bovine tuberculosis plays an important rôle.

So much for the contamination of butter by means of the tubercle bacillus. Investigations of recent years have directed us with ever-increasing frequency to the milk-supply as the source of epidemics of typhoid fever, scarlet fever, diphtheria and possibly some other of the infectious diseases. It is difficult to be precise in a discussion of scarlet fever; however, as regards typhoid fever we can adduce some interesting facts to illustrate the lesson of this article. If milk is infected with typhoid bacilli, these organisms will rise with the cream and be incorporated in the butter,[2] as we saw was the case with tubercle bacilli. It has, furthermore, been demonstrated by Bruck[3] that typhoid bacilli can maintain their viability and virulence in butter for at least twenty-nine days, and, indeed, multiply in this medium for the first few days.

In this connection it may be well to consider some phases of this topic which bear directly on our subject. It is claimed by some that the salting of the butter and its maintenance in cold storage kill the bacteria and render it a safe product. This question must still be considered an open one, in that a precise answer as to the exact influence of these factors on butter cannot be given. The consensus of opinion, however, seems to be that the addition of from 2 to 3 per cent. of salt, which is the usual salt content of commercial butter, has but a mild inhibitory effect on bacterial life or growth, and that in spite of the salt and the temperature of zero centigrade, bacteria have been found to multiply. These experiments record the results of bacterial counts of a gram of butter, and concern themselves with the estimation of lactic acid and other saprophytic bacteria. Such figures have little value for us, as we are concerned only with the viability of pathogenic organisms, such as the typhoid bacillus. As far as I have ascertained, a thorough study of this organism in this regard has not been made.

The attitude of the community toward butter and milk may be stated as follows: The people are warned not to drink milk unless it is certified or pasteurized; that is, unless it is pure or purified, on account of the danger of tuberculosis, typhoid, and other infectious diseases. Nevertheless they are urged to partake of butter which may well have these same pathogenic bacteria, but which by our silence we seem to concede is innocuous. It may be thought that the danger is slight because the amount of butter ingested is comparatively small. But, although this no doubt mitigates the evil, it does not by any means do away with it. I have shown elsewhere[4] that partaking daily of milk containing small numbers of tubercle bacilli may cause infection, whereas the same quantity given in one dose failed to produce tuberculosis. It should also be borne in mind that very young children, 2 years of age or younger, at a time when they are still very susceptible to infection by the bovine bacillus, consume considerable quantities of butter, and are thus exposed to infection.

When we come to consider the remedy of this evil, an evil which I realize is secondary to that of infected milk, we are met by the same difficulties and problems which beset us in the consideration of the milk problem—the ideal of a clean product which we can certify, and the practical makeshift of a safe product which we must permit. The certification of butter should impose the same requirement as the certification of milk, specifying

besides that the butter be made under clean and sanitary conditions. The demand for certified butter could never be general, for just as the price of certified milk is prohibitive to many a householder, so it would be in the case of the butter. But there are many who, if told of the dangers of the ordinary butter, of its contamination by tubercle bacilli and possible other pathogenic organisms, would be quite ready to pay the additional price for the surety of having a safe product for their children. It would be a butter for children, just as the certified milk is primarily a milk for infants and children. Some dairy which has butter-making machinery, especially one situated at some distance from the railway and therefore handicapped in selling its product as milk, might be induced to put a certified butter on the market. In proportion to the amount of milk used in making butter, butter is less expensive than milk; in fact, this is one of the exceptional cases in which the manufactured product brings less than the raw material. I hope to see this idea carried out in the near future, and do not doubt that some one will be found to enter this field.

Although a certified butter is out of the reach of the masses at the present time, a pasteurized butter, which is the other form of safe butter, is well within their reach. It is noteworthy that in spite of the fact that so many of us realize the advantages of a pasteurized butter, that we know that it is the staple butter in some countries, for example, Denmark, and is used in many other countries, that we have not been able to create a sufficiently strong demand to force the supply of this product. I need not add that pasteurized butter has no distinctive taste, and in color, texture and other qualities is no different from unheated butter. I believe that it is high time that it be rendered possible to purchase a labeled pasteurized butter, especially for the use of children. In New York a butter of this kind will be put on the market in the near future, and will cost five cents more per pound than the raw butter. This increase in price is permissible at this time; however, I do not believe that it will be found necessary when the demand is determined and found adequate. I believe that if our young children are protected from infection through butter we shall, in a very practical and simple way, be making another step along the road of preventive medicine.

THE DIAGNOSIS OF PANCREATIC DISEASE

L. G. HEYN, M.D.
Junior Staff Physician, Cincinnati Hospital; Instructor in Medicine, University of Cincinnati
CINCINNATI

In spite of the progress made in the knowledge of the physiology of the pancreas, its diseases remain difficult and uncertain of diagnosis. The cause of this is apparent in that the clinical aspects of pancreatic disease are in most instances indefinite and not characteristic, and many of the laboratory aids have not proved efficient. My desire to test the value of the newer methods devised for diagnosis prompted some work along this line in the Klinik von Noorden, in which I was associated in the work with Docent Dr. Salomon.

The newer methods of determining the pancreas function for diagnostic purposes aim to test for the presence of the ferments in the stool. To facilitate rapid peristalsis after a breakfast of mixed food followed by an enema, calomel 0.2 gm. and phenolphthalein 0.5 (as recommended by Muller) prove very satisfactory.

The two ferments made use of in the determination from the stool of pancreas activity are trypsin and amylopsin and their absence from the stool would point toward pancreas obstruction or insufficiency.

To determine the presence or absence of trypsin, the Fuld-Gross method may be used or the methods of Muller[1] and Schlecht,[2] which latter is as follows: The stool is rubbed up with a small quantity of glycerin to prevent evaporation, and several drops of the mixture placed in Petri plates containing Loeffler blood-serum and heated to 50-60 C. for twenty-four hours. The high temperature prevents the growth of bacteria, but not the action of the enzymes, and the presence of softening and depressions in the serum would indicate trypsin digestion, varying in degree according to the quantity of the enzyme present.

The simplicity of this method would commend its use, but already Schlecht has reported negative findings in the fat-stools of icterus, in obstipation, bloody stools and stomach carcinoma, and Komarelli has reported like observations. Frank and Schittenhelm[3] contend that the *succus entericus* also contains a proteolytic ferment, which would seem to place a doubtful value on these tests for the trypsin content.

The Fuld-Gross-Goldschmidt method (reference below) requires a solution containing 1 gm. each to the liter of casein, chloroform and sodium carbonate. To 5 c.c. of this solution varying dilutions of stool filtrate are added in different test-tubes, or, in the absence of a fluid stool, 5 gm. of stool is rubbed up with 20 c.c. physiologic salt solution, centrifuged and filtered and added to the casein solution. The mixture is allowed to digest at 38 to 40 C. for twenty-four hours, and the end-result is tested by the addition of a 1 per cent. acetic acid solution, which causes a precipitate in the tubes, when digestion is incomplete. The Fuld-Gross method proved very satisfactory in our work in the hospital and was carried out at the same time as the Wohlgemuth[4] method for amylopsin. The method of Wohlgemuth requires a 1 per cent. solution (Kahlbaum's soluble starch), which is best prepared on a water bath for eight to ten minutes with considerable stirring. Similar dilutions of stool filtrate as in the Fuld-Gross method are added to 5 c.c. of the starch solution in test-tubes, toluol added and the whole digested for twenty-four hours at from 38 to 40 C. At the end of this time the test-tubes are filled to near the top with tap-water, one drop of tenth-normal iodin solution is added to each tube, and a blue color no longer appears in the tube when the starch has been entirely digested. The dilution of stool used for both the trypsin and amylopsin tests are the same and are made with physiologic salt solution. In dilutions of 1 to 10, 1 to 100, 1 to 1,000 they are sufficient for all purposes. Of each of these dilutions it is best to take 2 c.c., 1 c.c. and 0.5 c.c., which are added to the tubes containing either casein or starch. The quantitative estimation of the ferment content is reckoned from the tube containing the greatest dilution, which has still been able to transform the starch or casein. The estimation is made in units, one unit representing the ability of 1 c.c. stool filtrate to transform 1 c.c. starch or casein solution. Suppose that the tube containing 1 c.c. of the 1 to 1,000 dilution is the greatest dilution which can transform 5 c.c. of starch solution; then 1 c.c. of undiluted filtrate would thus be able to digest 5,000 c.c. of starch solution, which would represent 5,000 units, a normal finding. The number of units usually ranges between 500 and 5,000, though cases may show 10,000 units and even higher, and 100 units may be considered the minimum. In my tests the non-pancreatic cases did not fall below 250 units, while the greatest interest attached to those giving a smaller number of units, which pointed to a deficiency of pancreatic secretion.

[4] Biochem. Ztschr., 1909, xxi

Wohlgemuth tied off the pancreatic ducts of a dog and found by his starch test that the stool contained a minimum quantity or practically no diastatic ferment. By means of a Thiry-Vella fistula, he found that the amylopsin of the *succus entericus* was very small in comparison with that of the pancreatic juice, and inferred that the amyloptic ferment present in the stool was in great part pancreatic.

Wynnhausen[5] worked with the Wohlgemuth methods, and in four cases of pancreas disease his findings were confirmative in giving results under 50 units. In two cases he worked simultaneously with the Fuld-Gross method and found low values in both tests.

Hirschberg[6] also found Wohlgemuth's method reliable in finding scanty diastatic ferment in the stool of pancreatic patients, at the same time finding by similar methods the increase of the ferment in the urine.

My clinical results with these methods may be given briefly as follows: My first attempts were with the Wohlgemuth methods of estimating the diastatic ferments in the stool. In the beginning the results were unsatisfactory and I soon detected the cause of this in the character of the cathartic used in order to obtain fluid stools. Rhubarb, cascara and the aperient waters frequently gave negative results, until calomel and phenolphthalein, as suggested by Muller, were used. In fifty non-pancreatic cases the stools showed ferment values ranging from 500 to 10,000 units. These cases included heart (compensated and uncompensated), diarrheas, stomach and intestinal neuroses, cardiospasm, organic nervous diseases, diabetes, and in nine cases of icterus, which were of special interest, the ordinary catarrhal icterus showed a normal range of value. A malignant jaundice which was suspicious of a pancreas obstruction, with much fat and muscle fiber in the stool, showed a value of 500 units, and at autopsy showed the disease limited to the bile passages and no pancreatic lesion. In a second case, which appeared at first malignant, 10,000 units were found, and pancreas disease was correctly excluded by subsequent history. The pancreas diseases were as follows: 1. Acute pancreatitis with necrosis, which came to operation in the Klinik Hochenegg, showed a value of 25 units. 2. Malignant icterus (Klinik von Noorden), 20, 25 and 100 units. Autopsy disclosed carcinoma of the pancreas head and of the bile-passages. 3. Malignant icterus (Klinik von Noorden), the patient operated on in the Klinik von Eiselberg, showed a value of 20 to 25. Exploratory operation revealed the entire region of the bile-passages, duodenum and pancreas head entirely matted together. No further exploration was attempted and the patient was taken home shortly after operation. 4. Acute pancreatitis (Klinik von Eiselberg), patient operated on four weeks previously, healed, with no disturbance of digestion or gross changes in stool, showed 5,000 units. 5. Pancreatic cyst operated on by Dr. Joseph Ransohoff (Cincinnati Hospital) gave 25 units.

These results would tend to show that considerable reliance may be placed on these methods.

Low unit values with both the Wohlgemuth and Fuld-Gross methods alike seem to point to a pancreatic obstruction or insufficiency.

The two tests mentioned have a rational basis and commend themselves also on account of their simplicity.

22 West Seventh Street.

DEATH OF FETUS DUE TO TWISTING OF CORD IN UTERO

H. W. FROEHLICH, M.D.
HIBBING, MINN.

The following case is reported with the idea that it may be of interest to some medical men who have had similar cases.

The patient was 18 years old, of Finnish nationality, pregnant for the first time, in good health and had always felt well. When six months pregnant, she noticed that there seemed to be no life. On examination no fetal movements could be detected. Rest was advised, and two days afterward labor pains came on. No effort was made to check them and in four hours the fetus, which apparently had been dead three or four days, was born. The cord was about 18 inches long. About 6 inches from the placental attachment, the cord had been twisted into a hard knot. From the placenta to the knot, the cord was normal. Beyond the knot to the fetus, the cord was beginning to shrink away and had been dead for a number of days. No other abnormal conditions were observed and to my mind it was merely a case in which the twist had shut off the blood-supply and killed the fetus. This patient lived in a second story and thus had to climb the stairs very often, also having to carry her own wood and water. This may have had something to do with the twisting of the cord.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

LIQUID NITROUS OXIDE—Nitrosum oxidum liquefactum.—Liquid nitrous oxide is dinitrogen monoxide, N_2O, in the liquid state.

Liquid Nitrous Oxide is a colorless mobile liquid, boiling at –89.8 degrees C. and solidifying at –102 degrees C., and having a sp. gr. of 0.937 at 0 degrees C. Liquid nitrous oxide returns to the gaseous state when the pressure is reduced and the temperature raised. The gas obtained from liquid nitrous oxide should have the properties of and respond to the following tests: It should be colorless, have a faint odor and a slightly sweet taste; it should not be inflammable, but should support combustion; it should be soluble in one volume of water at ordinary temperatures. No reaction should occur when 4 liters of the gas to be tested is passed slowly through each of the following: barium hydroxide solution, neutral litmus solution, silver nitrate solution, potassium iodide solution containing starch solution and alkaline mercuric potassium iodide solution.

If nitrous oxide gas be shaken in a gas burette with an alkaline solution of pyrogallol, the contraction in volume should indicate not more than 2 per cent. oxygen.

If nitrous oxide gas, after removal of the free oxygen be exploded with hydrogen gas in a Hempel gas apparatus, the reduction in volume should be at least 94.9 per cent. of this oxygen free gas, indicating not less than 93 per cent. dinitrogen monoxide, N_2O, in the original material.

---

[5] Berl. klin. Wchnschr., 190, No. 300; 1910, No. 11.
[6] Deutsch. med Wchnschr., 1910, No. 4.

If the above quantitative estimations be made in nitrous oxide gas, the residue of nitrogen gas should not exceed 5.5 per cent.

Actions and Uses.—Nitrous oxide gas causes anesthesia by direct influence on the central nervous system, as well as by the production of asphyxia. After a few deep inspirations, the face assumes a deadly pallor and the patient becomes unconscious. It raises the arterial blood-pressure. The death-rate from this gas, used as an anesthetic, is less than 1 to 500,000.

The gas derived from the liquid nitrous oxide is applicable to produce anesthesia for brief operations. For more prolonged anesthesia, admixture with oxygen is used. It is also used for the purpose of introducing anesthesia with ether or chloroform.

Dosage.—Liquid nitrous oxide is obtainable, under pressure, in steel cylinders. The liquid is allowed to evaporate in the cylinder and the gas is inhaled by the patient from a suitable inhalation apparatus.

Pharmaceutical Preparations Accepted for N. N. R.

The following dosage forms of accepted proprietary articles have been accepted for N. N. R.:

Cargentos Aseptic Vaginal Tampons.—Colloidal Silver Oxide Aseptic Vaginal Tampons. Aseptic wool tampons impregnated with 0.325 Gm. (5 grains) of Cargentos. The tampons are contained in No. 10 thin gelatin capsules. A silk cord is attached to the capsule, permitting the ready removal of the wool.

Cargentos Dusting Powder.—Colloidal Silver Oxide Dusting Powder. A mixture containing cargentos 10 parts, purified talcum and magnesium carbonate sufficient to make 100 parts by weight.

Cargentos Ointment.—Ointment of Colloidal Silver Oxide. An ointment said to contain cargentos 1 part with anhydrous wool fat 9 parts by weight, put up in collapsible tubes.

Therapeutics

ALOPECIA: BALDNESS

Several different forms of this condition have been described, of which the following are the types.

Alopecia congenitalia is an exceedingly rare condition in which a child is born without any hair. Microscopic examination of the skin in some cases shows an entire absence of follicles. In other cases the follicles are present, and after weeks, months, or possibly two or three years, the hair grows, although it is usually finer and thinner than in the average child of the same age.

Another variety is *alopecia senilis,* in which the loss of hair is an accompaniment and an indication of the general atrophy of the tissues throughout the entire body.

There is the disease called *alopecia areata,* which is characterized by a complete falling of hair from limited areas of the scalp or other hairy portions of the body. This is a distinct disease, and will not be considered in this connection.

There remains the form of *alopecia prematura,* in which the patient loses more or less of the hair to which he has become accustomed, but in which this loss is not associated with the changes characteristic of old age. This form of premature baldness is customarily divided into two classes; the idiopathic and symptomatic. In the idiopathic form few causes can be found for the occurrence, while in the symptomatic form there will be found some pathologic condition of the scalp, or some disease which has affected the general nutrition of the entire body. Under the latter head may be included the falling of the hair which so frequently follows typhoid fever, and which has recently been discussed at some length in this department. Omitting at the present time a discussion of the other forms of alopecia, a few words will be said in regard to the common form of premature alopecia.

Recalling the anatomy of the skin, it will be remembered that the hair grows from the hair follicle, at the bottom of which is the hair papilla, which is supplied with capillary blood-vessels and nerves, and from which the new cells are developed which form the hair. These at first are soft, and later become hard and cohere so as to form the normal hair. Under abnormal conditions when the general nutrition of the body is impaired, and when in particular as an incident of this general impairment of nutrition the nutrition of the hair papillæ is disturbed, these new cells do not undergo their normal development, but, remaining soft, the hair drops out. If the impairment of nutrition is not permanent, a new hair will form. If, however, the impairment of nutrition continues, the opening of the follicle may finally be closed up, and then no further development of hair from that follicle will take place.

Various causes may give rise to this interference with development; various infectious diseases, especially the exanthemata, may do so. Erysipelas is a common cause of such interference with nutrition, as is also pregnancy. Various forms of mental and nervous disturbance, such as shock or worry, may also interfere with the development of the hair.

The causes which have been enumerated are general causes. There are, furthermore, a series of causes which are local in their action. Among these may be mentioned, as the most prominent cause, the occurrence of dandruff, which in most cases is due to a cutaneous disease variously designated as eczema seborrhoicum or dermatitis seborrhoica. There is even now some difference of opinion as to the ultimate cause of this seborrheic condition of the scalp, some attributing it to a microscopic organism, and others denying that such a cause has been determined. It must be admitted that very many cases of dandruff are seen in which apparently there is no special tendency to falling of the hair, but, on the other hand, it will be found that a very large proportion of patients who are losing their hair in this premature way are suffering from some form of dandruff, generally the seborrheic form.

TREATMENT

The treatment of baldness, whether due to a local inflammation of the scalp or to the result of some general disturbance of nutrition, is a somewhat puzzling matter. The treatment adopted must be continued for several weeks or even months before a result of much importance can be observed. Obviously at first the constitutional condition of the patient should be carefully inquired into, and any disturbance of it should be promptly remedied. If care and worry are apparently important factors in the disease, these should be remedied as far as possible. If the digestion is not properly performed, measures should be adopted which will correct it.

Certain internal remedies have appeared to have some control over the nutrition of the skin and scalp. Perhaps none surpasses arsenic in this respect, and in many cases the use of this drug will seem to contribute to a favorable result. If anemia is present, iron may be combined with arsenic. For instance:

℞	Gm. or c.c.		
Arseni trioxidi	04		gr.⅔
Massæ ferri carbonatis	2	or	ʒss

M. et fac pilulas 20.

Sig.—Take one pill, three times a day, after meals.

Another drug which has appeared to have a selective action on the skin and scalp is sulphur, and in some cases this drug has been given with benefit, especially if there is constipation, or if there is observed a tendency to suppurative inflammation of the skin.

The question of local applications to the scalp is one which must be approached with some hesitation. The variety of drugs which have been recommended for application to the scalp to stimulate the growth of the hair is so great that one naturally feels suspicious in regard to the value of any one. This, however, must not discourage the physician from trying to select a suitable one which will prove of benefit to his patient. If dandruff is abundant on the scalp, one of the simplest applications is a solution of borax, with glycerin and water.

℞	Gm. or c.c.		
Sodii boratis	4		ʒi
Glycerini	25	or	fl.ʒv
Aquæ	ad 200		ad fl.℥vi

M. et Sig.—Shake, and apply externally twice a day.

This, like all applications designed for use on the scalp for the purpose of stimulating the growth of the hair, should be applied to the scalp and not to the hair. This may be accomplished by using a comb to part the hair, separating it so that the application may be made directly to the scalp, and when the application has been made along one part, making successive applications along other parts, until the application has been made over the entire scalp.

Another remedy which has been extensively used for the relief of dandruff is resorcin. This may be used in the form of either a lotion or an ointment.

℞	Gm. or c.c.		
Resorcinol	6		ʒiss
Alcohol	75	or	fl.℥ii
Aquæ	ad 200		ad fl.℥vi

M. et Sig.—Shake and apply to the scalp twice a day.

Or,

℞	Gm. or c.c.		
Resorcinol	50		gr.x
Adipis lanæ hydrosi	25	or	℥i

M. et Sig.—Rub into the scalp twice a day.

These remedies are especially useful when there is any evidence of inflammatory action in the scalp because of their soothing and anti-inflammatory action. In these cases remedies which are stimulating should be avoided. If there is no evident pathologic process going on in the skin except the falling of the hair, more stimulating remedies may be applied. Of these the most important are alcohol, quinin, cantharides, and ammonia. These, with resorcin, which has been already mentioned, are the fundamental ingredients of most popular hair tonics. Bay rum, a favorite application to the hair with many people, owes its pleasant effect largely to the alcohol contained in it.

The tincture of cantharides is often combined with alcohol and castor oil as in the following prescription:

℞	c.c.		
Tincturæ cantharidis	10		fl.ʒii
Olei ricini	5	or	fl.ʒi
Alcoholis	ad 100		ad fl.℥iii

M. et Sig.—Apply externally.

When corrosive sublimate is used the proper strength is half a grain to an ounce (0.03 gm. to 30 c.c.) of alcohol.

Ammonia may be used, as in the following prescription of Erasmus Wilson:

℞	c.c.		
Aquæ ammoniæ fortioris	10		
Chloroformi	10		
Olei amygdalæ expressi	10	or	āā fl.℥ss
Olei limonis	3		fl.ʒi
Alcoholis	ad 100		ad fl.℥iv

M. et Sig.—Apply by dabbing on the scalp with a small piece of cloth, but not with friction.

The hydrochlorid of pilocarpin may be used in the form of an ointment:

℞	Gm. or c.c.		
Pilocarpini hydrochloridi	1		gr.xv
Olei lavendulæ	1	or	♏x
Petrolati	10		ʒiiss
Adipis lanæ hydrosi	30		℥i

M. et Sig.—Use externally.

A sulphur ointment may sometimes be used with advantage.

PROPHYLAXIS

It is apparently little considered by the average individual that the hair should receive as particular care as do the teeth and nails. To be sure, it is the custom of most people to comb their hair, but this is generally done for the cosmetic rather than for hygienic effect. By improper care of the hair great harm may be done, and conversely, people who desire to preserve their hair in good condition should take pains to encourage its healthy growth. Many people overdo the matter of making applications to the scalp, applying strong alcoholic preparations or other so-called tonics too frequently. Others, with an excess of pains, bathe it too frequently, especially with cold water, as is the case with people who take a daily cold shower bath. Others indulge too frequently in the luxury of a shampoo. While occasional washing of the hair is beneficial, too frequent application of water to the hair does harm by withdrawing the natural oil from the hair and scalp. The best authorities advise shampooing the scalp not more frequently than once a week and not less frequently than once a month. Probably nothing better can be used on these occasions than Castile soap and warm water.

It is a common belief, and appears to be well founded, that too closely covering the head has a bad effect on the growth of the hair. The stiff hats so commonly worn by men at the present day, which fit so closely about the head, and which are worn by many so constantly, it can readily be believed would have a bad influence on the hair. In the first place, the tight binding of the scalp must interfere with the circulation through the scalp and around the hair papillæ; and in the second place, the space in the crown of the hat must allow a considerable quantity of air to become heated above the temperature of the body, and this also must have a bad effect on the nutrition of the hair.

While a certain amount of sunshine and fresh air is probably beneficial to the hair, on the other hand, it is probably better that the hair and scalp should be protected from constant exposure to the rays of the sun and to the wind and dust.

With women, the case is somewhat different, but they have their special unhygienic practices which must be mentioned and condemned, especially the curling of the hair by winding it about hot curling-irons or doing it up in curl-papers over night.

In women, if the hair is found to be cracking at the ends and becoming thin and unhealthy, the ends should be cut off. Most men habitually have their hair cut frequently. Whether this is of advantage or a mistake is not so easily decided. There are good arguments on both sides.

SATURDAY, AUGUST 12, 1911

INFANTILE SPLENIC ANEMIA AND KALA-AZAR

Among the affections whose etiology is still more or less obscure, the so-called blood diseases occupy a prominent place. It has long been acknowledged that some of these which we now consider as entities may in reality consist of a group of distinct diseases, closely resembling each other clinically, but independent in causation. One such instance, indeed, is well known—that of infection with *Bothriocephalus latus* and its resulting anemia, distinguishable from "primary" pernicious anemia only by the presence of the parasite. Another somewhat similar instance has apparently been brought to light by a group of Italian investigators, in the splenic anemias of childhood. These may be differentiated clinically into a febrile and afebrile type; and in the former, at least as found in the Mediterranean valley, a parasite has been demonstrated with remarkable constancy. In 1905, Pianese first announced the finding, in various organs of patients with this disease, of organisms morphologically indistinguishable from the Leishman-Donovan bodies of kala-azar. Since then various investigators have amply confirmed this, and an inspection of the accumulated data as given in a recent article by Jemma and Di Christina,[1] leaves little doubt as to the accuracy of their conclusions. Strangely enough, the cases so far reported are limited to a rather narrow geographic environment—Sicily, the Liparic Islands, Calabria, Tunis and Malta; one case has recently been found in Lisbon. That the real distribution will finally prove to be so restricted is of course improbable; with wider dissemination of knowledge concerning the disease, a much wider range is to be expected, more especially as the two affections most likely to be confused with it, malaria and Malta fever, infest much the same districts. The peculiar form of infantile splenic anemia with fever, known as *ponos,* which is endemic in the two small islands of Spezzia and Hydra near the Peloponnesus, is clinically indistinguishable from this infection and proper investigation will very probably prove their identity.

Clinically, the disease is distinguished by splenic enlargement, anemia and irregular fever, and less characteristically by gastro-enteric disturbance, usually diarrhea, enlargement of the liver, in some cases hemorrhages from the mucous membranes and under the skin, and edema of the feet and ankles. The splenic swelling is very hard and may extend across the abdomen. The anemia may be quite marked and is characterized by a peculiar waxy pallor, though at times the skin may be earth-colored or subicteric. The color-index seldom varies much from unity; nucleated red cells are absent or very rare. Leukopenia, with predominance of mononuclear cells, seems to be the rule, though at times leukocytosis occurs. The fever is almost typical, inasmuch as there may be several exacerbations and remissions in the course of a single day. The disease, as a rule, runs a chronic course, lasting over months or years, and is subject to marked remissions, when fever is absent and the general condition improves temporarily. Although, as its name indicates, it was at first believed to be limited to infancy, recent cases have been reported in adolescence and early manhood. The ultimate diagnosis rests, of course, on finding the parasites, most conveniently as a rule by splenic puncture; their presence in the peripheral blood is disputed and is at best very rare.

As in the case of kala-azar, little or nothing is known of the contributing etiologic factors. Its sporadic occurrence, in neighborhoods apparently free from previous cases, precludes the idea of direct contact infection; and this, in connection with the protozoan character of the parasite, has directed attention to the possibility of intermediate animal hosts. The great majority of cases have come from among the poorer classes, mostly peasants and fishermen, all of whom are possessors of large numbers of dogs. Investigation of spontaneous infection of these has led to diverse results. In Tunis four of 253 animals were found infected, while in Palermo, like Tunis a site of the disease, none were found in 300 investigated. On the other hand, in Rome, where no human cases have hitherto been reported, sixteen of sixty dogs gave positive results. In regard to the possibility of an insect carrier, Patton's work on kala-azar, in which he found the Leishman-Donovan bodies infecting the bedbug, is of interest.

The identity of this type of splenic anemia with kala-azar is still a matter of dispute, which probably will not be settled until our knowledge of the parasites is considerably increased. In favor of the acceptation of a common organism for the two infections are the following points: first, the identity in morphology and distribution in the host of the parasites; second, the similar pathologic changes—splenic and hepatic enlargement, alterations in the bone-marrow, and intestinal ulceration; third, the chronic course, extending in both over months. On the other hand, the organism of the Mediterranean disease has been cultivated by one observer to indefinite generations on the Novy-MacNeal medium, while that of kala-azar has been so far grown only on citrated blood and for not over three generations. The Mediterranean organism has been inoculated into dogs, though, it is true, with some difficulty. Attempts to inoculate these animals with the organism of kala-azar have so far been unsuccessful, nor have any cases of spontaneous infection been found in some 1,000 dogs investigated. And finally, the almost complete limitation of the Mediterranean infection to childhood, and the occurrence of kala-azar at all ages, might argue against their identity.

---

[1] Jemma and Di Christina: Centralbl. f. Bakteriol., u. Parasitenk., 1911, lix, 109

It is not likely that any considerable number of cases will ever be found in the United States, where climatic and hygienic conditions are so different. Sporadic cases may quite possibly occur, however, and it behooves our American practitioners, particularly those whose work leads them much among the Italians, to be on the alert for them.

CIVILIZATION AND THE TROPICS

It has long been a matter of popular belief that tropical or subtropical regions are unsuited to the higher developments of civilization, and that the whip of more rigorous conditions is needed to awaken the sleeping elements of progress in man. The present-day distribution of civilization would seem to support this view. With few exceptions our most progressive communities are located in temperate regions; and, at least until recently, any invasions of the tropical and semitropical zones by representatives of our northern civilization have either suffered rapid decline, or have been kept vigorous only by constant reinforcement from their source.

It would seem that this superiority of the colder latitudes as a place for human development has not always existed. Almost without exception, the parent sources of human progress, so far as one can trace them, have been in tropical or at least in subtropical countries. Mesopotamia in Asia, Egypt in Africa, the eastern Mediterranean valley in Europe—all represent sites of apparently original civilizations, and are located well within the warmer zones. So, too, our indigenous American civilizations have been located wholly in the warmer latitudes of the continent. The mysterious relics of Central America and Mexico on the one hand, and of Peru on the other, are so situated. It is true that in this latter case the altitude is such as to change climatic conditions; but there is evidence to show that marked elevation has taken place here comparatively recently, and that the more ancient remains in this region actually antedate this elevation.

If, then, the tropics, originally the source of human culture, have been incapable of maintaining it, some change in condition must be responsible. One probable explanation, in view of recent experience, lies in the spreading of the peculiarly tropical diseases, due to the increased exchange of people and products so characteristic of later years. The decline of Greece and Rome has been ascribed to the introduction of malaria along with African slaves, and in our own continent we have an even better-established instance of this sort. Torquemada, speaking of Yucatan, itself a site of prehistoric American civilization, says: "Men die of pure old age, for there are none of those infirmities that exist in other lands; and if there are slight infirmities, the heat destroys them and so there is no need of a physician there." But with the coming of the white man and negro and their alien diseases, conditions changed until southern Mexico and Central America became notorious as hotbeds of tropical fevers.

With progress in sanitary science, this position of the warmer latitudes promises to undergo another alteration. Already in Cuba and Panama the possibility of mastery over these diseases has been shown, and it is only a matter of time until the methods and results attained there have a world-wide application. When this has occurred, will the warmer latitudes resume their old relationship as forcing-beds of human progress, or will they retain their present minor importance? It may well be, even with elimination of special disease, that the warmer climate will be unsuited to the white man, with his centuries of habituation to a colder sun. In that case, will our darker-skinned brother, free from the handicap of disease, take up the torch in his turn again? The problem has its philosophical as well as practical interest, and on the manner of its solution will depend in large measure the fate and character of future man.

THE PURITY OF ANESTHETICS

While pharmaceutical chemists work untiringly in attempting to discover new compounds that may be of use in medicine, there seems to be a disinclination to study those already discovered with a view to improving their quality. At least, those chemists who could render most efficient service are but rarely attracted by such work. The result is that studies on the purity of drugs in common use are usually left to those who are commercially interested in them or to the overworked federal or state authorities who, as best they can, safeguard the health of the people by watching for the grosser adulterations.

But many drugs and medicines are sorely in need of a careful scientific study, both as to their purity and as to the effects of various impurities on their medicinal action. The painstaking investigations which these drugs require might well attract the scientific workers in universities. The composition of anesthetics—drugs in which small amounts of impurities may have serious effects—is an illustration. We have previously called attention to the valuable service rendered by the Council on Pharmacy and Chemistry, when it secured the investigation of commercial brands of compressed oxygen.[1] In the Propaganda for Reform department of this issue, the Council gives the results of an examination of commercial nitrous oxid, by Professor Smith of the Lewis Institute.

---

[1] Smith, W. R., and Leman, E. D.: THE JOURNAL A. M. A., March 18, 1911.

In this connection, attention should also be called to similar work that is being independently pursued by Professor Baskerville of the College of the City of New York. Professor Baskerville is making an exhaustive study of the purity of oxygen and of anesthetics—a piece of work which should do much to increase our knowledge of anesthesia, and which should materially lessen the accidental deaths arising therefrom. So far he has published reports on ether, oxygen and nitrous oxid, and it is interesting to note that his findings and the tests for purity which he proposes for compressed oxygen and liquid nitrous oxid,[2] are in close accord with the findings of Professor Smith and the standards adopted by the Council on Pharmacy and Chemistry of the American Medical Association. Let us hope that other investigators may realize that a reinvestigation of many old subjects is well worthy of their attention and perhaps of vastly more importance to public welfare than the ceaseless search for new substances.

Current Comment

TEXAS DECISION ON "UNPROFESSIONAL CONDUCT"

In another department[3] appears an abstract of the decision of the Court of Civil Appeals of Texas, affirming the action of the State Board of Medical Examiners revoking the license of J. Lafayette Berry. According to the evidence in the case, Berry advertised himself as a physician especially skilled in the treatment and cure of gall-stones. To those confiding persons who paid him in advance as much as they were able to secure he administered olive oil and epsom salts, thereby converting these persons into perambulating soap factories, guaranteed to produce large quantities of "gall-stones" on short notice. This fraud has already been exposed in The Journal.[4] The court held that such methods were "grossly unprofessional and dishonorable, and of a character likely to deceive and defraud the public," that the board was warranted in revoking Berry's license and that the lower courts were right in sustaining the action of the board. The attorneys for the defense pleaded that the law did not define unprofessional and dishonorable conduct; that representatives of other "schools" of medicine than the defendant were not competent to testify against him and that violation of the "code of ethics" of the medical profession was not a crime in Texas. The court, however, made short work of these pleas, saying, "His [Berry's] testimony alone was sufficient to justify the jury in finding that his treatment was a fraud and that he knew it and also knew that the material passed by his patients which he pronounced gall-stones was not actually gall-stones. . . . When the unprofessional conduct of a member of the medical profession is of such a character as to deceive and defraud the public then the law denounces such conduct and strips the offender of the means which makes it possible to impose on the credulous and unwary." J. Lafayette Berry has, we are informed, disappeared from Texas since his conviction. We do not know in what state he will resume the wholesale soap business, but we respectfully commend him to the tender care of the various state boards of medical examiners, feeling sure that sooner or later J. Lafayette will once more yield to a desire to relieve his victims of "gall-stones" (and cash). Should he at any time put in an appearance some interesting facts regarding his professional history may be secured from the attorney for the Texas State Board of Medical Examiners.

A TRUST WHICH DESERVES ENCOURAGEMENT

In a recent speech in the United States Senate, Hon. Robert L. Owen of Oklahoma, in an argument for a national Department of Health, said, after reading the recent editorials of *Collier's Weekly* into the record: "Mr. President, the American Medical Association has published at great length scientific and careful analyses of most of the nostrums and patent medicine frauds of this country. They have given wide publicity to it and in that way they have excited the violent animosity and hostility of the patent medicine people so that the declaration is made by them that the medical profession comprises a trust. In point of fact, if the American Medical Association forms a trust and if they are concerned in establishing a Department of Health with a view to preventing sickness, which would be the purpose of the Department of Health, they would be engaged in tearing down their own business; they would be engaged in depriving themselves of their patients from whom they make their living. It would be the only trust in existence which is concerned in diminishing its own revenues and destroying its own financial foundation. Such a trust as that is a very noble trust and one that deserves encouragement." It might also be of interest to our readers to know that when Senator Owen asked permission to insert the *Collier* editorials in the record, Senator Gallinger of New Hampshire was the only member of the senate who objected. Senator Gallinger is also the only member of the United States Senate who claims a medical degree.

THE PROGRESS OF CREMATION

Cremation in the present-day manner seems to have had its inception in 1866. There are now about eighty crematories in Europe; twenty-two are in Germany, seven in Switzerland, and thirty in Italy. About 13,000 bodies were cremated in Europe during 1909. Many Americans have died in Europe, whose bodies have been cremated, the ashes having been sent to their American homes for inurning or burial. In 1874 the Cremation Society of England was founded, Sir William Thompson being made its first president. There are now at least thirteen crematory furnaces in England in which, during 1909, more than 800 bodies were burned. Cremation is thus a legal procedure in that country. In the United States 13,012 cremations were recorded between the years 1876 and 1900. The number of crematories is steadily increasing; it is not rare to see among the tombs in cemeteries, columbaria, where the ashes of other dead are inurned. In Boston the idea of substituting crematories for potter's fields has long been agitated; this might well be done in all large cities, with obvious advantages and with no essential disadvantage of any kind whatever. At quarantine in New York harbor the bodies of immigrants who have died of infections are (in accordance with the statutes) burned on Swinburne Island in the lower bay; though this is not done if the relatives have religious scruples against cremation. In New York state a person may direct what is to be done with his body, provided the disposal be consistent with propriety and decency. And such is no doubt the prevailing sentiment and legal status of the matter in American communities.

Medical News

CALIFORNIA

A New Case of Plague.—A case of bubonic plague, said to have been transmitted by ground squirrels, is reported from Contra Costa County. The patient, 7 years of age, is reported to have died July 26, after having been scratched and bitten by a ground squirrel.

Changes in Stanford Faculty.—The following appointments have been made in the Medical Department of Leland Stanford Jr. University: Dr. Thomas Addis, Carnegie Research scholar, F.R.C.P., Edinburgh, assistant professor of medicine, to have charge of the work in clinical chemistry; Dr. James Eaves of Edinburgh and Guy's Hospital, London, instructor in surgery, to have charge of surgical pathology; Drs. George Lyman, W. H. Banks, William R. P. Clark, Walter Schaller and W. H. P. Luttrell, assistants in the medical dispensary, and Drs. W. Winterberg and Isaac Walton Thorne, assistants in the surgical dispensary. Provision has also been made for the appointment of an academic professor of obstetrics and gynecology.

Personal.—Dr. Fred Baker, San Diego, who went to Brazil as physician of the Leland Stanford Jr. university expedition, expects to return by the way of Panama, next month.——Dr. Phil. Abbott, Piedmont, has returned from Europe.——A bomb was exploded on the front porch of the home of Dr. Charles A. Davis, Pasadena, July 16.——Dr. William V. Brem has accepted the chair of pathology in the University of California, Los Angeles, and will open a clinical laboratory in connection with Dr. Avrum H. Zeiler.——Dr. P. S. Goodmann, Sutter Creek, is recovering slowly from burns sustained a few days ago when his sanatorium was burned.——Dr. John Wesley Trueworthy is reported to be critically ill at his home in Los Angeles.

COLORADO

Church Opens Hospital.—The Methodist Church of Colorado Springs has rebuilt and opened Bethel Hospital at a cost of $25,000.

Opium Smuggled.—Custom officers report that large quantities of opium are being smuggled into Pueblo, Colorado Springs and Denver by proprietors of opium dens. In a raid lately made by the Denver police, 125 pounds of opium was found and confiscated.

Personal.—Dr. and Mrs. Edward Jackson, Denver, are spending the summer in Great Britain.——Dr. Perry F. Perdue, Sterling, who was recently operated on for appendicitis, is convalescent.——Dr. Lewis E. Lemen and Dr. Josiah N. Hall, Denver, and Dr. Vivian Russell Pennock, Longmont, have resigned from the State Board of Health.

GEORGIA

University of Georgia to Assume Control of the Medical School at Augusta.—The bill authorizing the University of Georgia to take over and assume full control of the Medical College of Georgia, Augusta, was passed by the Georgia legislature and has been signed by the governor. This will mean extensive improvements in the medical school at Augusta.

IOWA

Health Train for Iowa.—The State Board of Health is planning to equip a state health train which will commence a thorough propaganda on the lines initiated by Louisiana. The chief purpose will be to bring into the home knowledge of more sanitary methods of living, to give practical everyday health hints for the home, and to spread the antituberculosis campaign.

Personal.—Dr. David Carson, Council Bluffs, has been elected secretary of the Council Bluffs Medical Association, vice Dr. John Frederick Sprink, deceased.——Dr. John H. Crippen, Waterloo, is reported to be critically ill at his home.

KANSAS

State Board Elects.—At the June meeting of the Kansas State Board of Medical Examiners, Dr. Albert S. Ross, Sabetha, was elected president and Dr. Henry A. Dykes, Lebanon, secretary.

Personal.—Dr. Samuel M. Myers, Potter, is reported to be seriously ill as the result of an automobile accident in Easton, July 26.——Dr. Willard A. Phares, Wichita, has returned after a year abroad.——Dr. William T. McKay, Arkansas City, for several years physician to the Chilocco Indian School, has resigned.

Does Not Approve Madstone.—At the request of Dr. Samuel J. Crumbine, secretary of the State Board of Health, the attorney general has ordered the arrest of the owner of a madstone in Hutchinson, if he endeavors to use it in an effort to cure a boy who was bitten by a dog in Winfield a few days ago. The county authorities have been instructed to find the boy and have him sent to the State University Hospital, Rosedale, where Pasteur treatment will be administered.

MARYLAND

Baltimore

New Laboratory Building.—A three-story building will be erected in the rear of the Baltimore Medical College, 22 by 68 feet, and at a cost of $3,000, to be used for laboratories.

Personal.—Dr. G. Halstead Boyland, who is now traveling in Europe, sails for home, August 16.——Dr. Christian Deetjen, who recently underwent an operation for prevention of cancer of the skin due to exposure to *x*-rays, is reported to have recovered.——Dr. Thomas C. Bussey, Texas, Baltimore County, is reported to be critically ill on account of a cerebral hemorrhage.——Bishop Luther B. Wilson, M.D., who has been seriously ill with fever contracted in Portuguese East Africa, is reported to be convalescent.

Corrections.—Attention has been called to three errors in the news from Maryland: In the item "Portrait of Old Physician," Dr. William J. Todd, Mount Washington, is the chairman of the committee, and not Dr. William Tarun of Baltimore, as stated on page 401 of THE JOURNAL of July 29, and the name of the society should be "Baltimore County Society" and not "Baltimore Medical Society."——In THE JOURNAL of August 5, page 488, the item entitled "Fund Raised for Pathology" states Dr. John Randolph Winslow as the one through whose efforts a large sum of money was added to the maintenance fund. The credit of this work should be given to Dr. Randolph Winslow.

MICHIGAN

Upper Peninsula Physicians Meet.—At the annual meeting of the Upper Peninsula Medical Society, held in Escanaba, July 27-28, the following officers were elected: president, Dr. Charles L. Girard, Escanaba; vice-presidents, Drs. Edward Sawbridge, Stevenson, and Alfred W. Hornbogen, Marquette, and secretary, Dr. Calvin R. Elwood, Menominee. Menominee was selected as the next place of meeting.

New County Societies.—The physicians of Cheboygan met July 25, and organized the Cheboygan County Medical Society. The following officers were elected: president, Dr. Wilbur F. Reed; vice-president, Dr. Willis E. Chapman, and secretary-treasurer, Dr. Charles B. Tweedale, all of Cheboygan.——Alpena County Medical Society has been reorganized with the following officers: president, Dr. James D. Dunlop; vice-president, Dr. Edward E. McKnight, and secretary-treasurer, Dr. Clarence M. Williams, all of Alpena.

MISSOURI

Personal.—Dr. Norman F. Terry has been elected president; Dr. Theodore A. Coffelt, vice-president; Dr. Robert L. Pipkin, secretary, and Dr. Lee Cox, treasurer, of the Springfield Hospital Association.——Dr. and Mrs. Joseph J. Carter, Weston, have gone abroad.

Changes in State Hospital Staff.—The board of managers of State Hospital No. 4, Farmington, has elected Drs. William S. Hutton, Fornfelt, and John A. Tiller, Bloomfield, assistant physicians at the institute, vice Drs. Henry Lloyd and F. S. Weber.——Dr. James A. Waterman, head physician of the State Penitentiary, Jefferson City, has been elected superintendent of State Hospital No. 4, Farmington, vice Dr. Robert S. McGee, Green City, appointed assistant superintendent of State Hospital No. 1, Fulton.

Medical Staff Assigned.—At the regular meeting of the board of control of Levering Hospital, Hannibal, the following assignments for the year were made: physician in charge, Dr. John N. Baskett; attending surgeon, Dr. Thomas Chowning; consulti [illegible] Henry L. Banks and Charles E. Paxon; [illegible] Dr. Elmer E. Waldo; consulting physicians, Drs. John J. Farrell and W. Cloyd Guss; attending gynecologist, Dr. William H. Hayes; consulting gynecologists, Drs. Isaac E. Hill and Richard M. Winn; attending obstetrician and pediatrist, Dr. John J. Farrell; consulting obstetricians and pediatrists, Drs. William H. Hays and Thomas C. Procter; attending genito-urinary surgeon, Dr. Richard Schmidt; consulting genito-urinary surgeons, Drs. James F. Cooper and W. Cloyd Guss; pathologist, Dr. Mary S. Ross; attending oculist and aurist, Dr. James S. Howell; consulting oculists and aurists, Drs. Edward T. Hornback and Ulysses S. Smith, and roentgenologist, Dr. Isaac E. Hill.

St. Louis

Medical Reserve Corps Organized.—The officers of the Medical Reserve Corps, U. S. Army, located in St. Louis, met July 12, and organized the St. Louis Society, Medical Reserve Corps U. S. Army, adopted a constitution and by-laws and elected the following officers: president, Lieut. Harvey G. Mudd; vice-president, Lieut. Walter C. G. Kirchner; secretary-treasurer, Lieut. William H. Luedde, and executive committee, Lieuts. William A. Hardaway, Amand N. Ravold and Frederick C. E. Kuhlmann. At a special meeting of the society held at Jefferson Barracks, July 12, Lieut.-Col. Jefferson R. Kean, M.C., U. S. Army, outlined the history of the development of the Medical Reserve Corps, and detailed its purposes and functions.

MONTANA

Personal.—Dr. W. A. Halbush, Cut Bank, has been appointed local surgeon of the Great Northern System.——Dr. John McIntyre, Butte, was seriously injured recently by being thrown from his carriage.——Dr. Albert F. Longeway, Great Falls, has been elected vice-president of the University Club.——Dr. J. Rudolph E. Sievers and family, Butte, are spending the summer abroad.

NEBRASKA

Personal.—Dr. William D. Gibbon, Lorton, was seriously injured in an automobile accident, July 13.——Dr. Leo A. Dermody, Omaha, was operated on for appendicitis, July 25.

New Officers for Board of Secretaries.—The Board of Secretaries of the State Board of Health has reorganized with the following officers: president, Dr. Herschell B. Cummins, Seward; vice-president, Dr. E. Arthur Carr, Lincoln; secretary, Dr. Clifford P. Fall, Beatrice, and treasurer, Dr. Porter F. Dodson, Wilber.

Quarterly Meeting of County Society.—At the third quarterly county meeting of the Dawson County Medical Society, held at Cozad, June 30, the address of the evening was given by Dr. Harry M. McClanahan, Omaha, who spoke on "Summer Diseases of Children." The next meeting will be held at Cozad in October.

State Sanatorium Purchased.—The Grothan Sanatorium, Kearney, known as Elmwood Place, has been purchased by the state as a tuberculosis sanatorium for $24,000. The remainder of the appropriation of $40,000 will be used for the necessary remodeling and improvements. An appropriation of $10,000 has also been made by the legislature for maintenance.

NEW YORK

Gift to Hospital.—Mrs. Harriet M. Biglow has given $1,000 to be added to the endowment fund of the Corning Hospital. This institution now has an endowment fund of $37,000.

Food Commission Appointed.—Governor Dix has appointed a New York Food Investigating Committee. In addition to a number of lay members Dr. Eugene Porter, State Health Commissioner; R. A. Pierson, State Commissioner of Agriculture; Dean Bailey, Director of the State College of Agriculture, and Whitman H. Jordan, Director of the New York State Agricultural Experiment Station, have been appointed to serve. All members are to serve without compensation and are authorized to inquire into the purity, prices, production, distribution and consumption of foodstuffs and farm and dairy products and to recommend remedial legislation next year.

New York City

Personal.—Dr. Hubbard W. Mitchell and Dr. and Mrs. Livingston Farrand have sailed for Europe.——Dr. George Gibier Rambaud was seriously injured in an automobile accident near Poughkeepsie on August 2.

Danger from Cholera Passed.—There were on August 5 only three cases of cholera remaining on Swinburne Island, while two weeks earlier there were eighteen cases. During this time fifteen patients have been discharged as cured. The Health Officer of the Port, Dr. Doty, expresses the belief that the danger of a cholera invasion is at a minimum.

Fewest Deaths in Thirteen Years.—The mortality for the week ended July 29 is the lowest, for a corresponding week, reported since 1898, being 14.10 per 1,000 and is 23 per cent. less than for the corresponding week of last year. The decrease occurred in all age groups. The deaths of infants numbered 375 as compared with 575 for the corresponding week of last year.

NORTH DAKOTA

Begin Work on Sanatorium.—The board of trustees of the state tuberculosis sanatorium, to be located at Dunseith, met July 19 and decided on plans for the building which is to cost $25,000, and which will be erected as soon as practicable. The building will be 42 by 50 feet, and two stories and a basement in height. In addition a cottage to cost about $3,000 will be erected, containing outdoor sleeping-rooms for patients.

New Examining Board.—The governor has named the following physicians as members of the State Board of Medical Examiners, following the recommendations of the North Dakota State Medical Association: Drs. Henry G. Woutat, Grand Forks; Arthur G. Patterson, Lisbon, and Francis R. Smyth, Bismarck, for one year; Drs. Albert W. Skelsey, Fargo; Francis Peake, Jamestown, and George M. Williamson, Grand Forks, for two years; and Drs. Paul Sorkness, Fargo; Alexander J. McCannel, Minot, and John E. Countryman, Grafton, for three years.

OKLAHOMA

Personal.—Dr. John W. Riley has resigned from the health board of Oklahoma City.——The office of Dr. Daniel David Roberts, Nashville, was burned in a fire which caused a loss of $15,000 to that village recently.——Drs. Richard Stephen McCabe and George Hunter, Oklahoma City, have been appointed assistant city physicians of Oklahoma City, vice Drs. Joseph T. Martin and Robert Elmore Looney.——Dr. Albert R. Hughes, Indiahoma, has given up the practice of medicine to return to his former profession of the law.

OREGON

New Nurses' Home.—The site for the nurses' home at the Multnomah Hospital, Portland, has been selected. The building will be on ground owned by the county and will cost $13,340.

Personal.—The ranch home of Dr. George Calvin Skinner, Hamilton, O., at Hood River, Ore., was burned to the ground, July 27.——Drs. Andrew C. Smith, Rupert J. Chipman and George Burnside Story have been reappointed members of the Portland Board of Health and Dr. Glenn W. Wheeler has been retained as health officer.

PENNSYLVANIA

Anti-Spitting Law Observed.—State Health Commissioner Dixon notes with satisfaction that in the stations of the state the railway platforms are perfectly clean and free from spit, showing that the railway companies are enforcing the state anti-spitting law and the people also are observing it.

Personal.—Dr. James M. Torrence, Indiana, is reported to be seriously ill with appendicitis.——Dr. Evan J. Groom, Bristol, was thrown from his carriage in a collision with an automobile and was seriously injured.——Dr. David Nathan, Norriston, had a narrow escape from drowning in Perkiomen Lake, July 26.

Governor Appoints Trustees.—Governor Tener has appointed the following as trustees of the State Institution for the Feeble-Minded of Eastern Pennsylvania: Dr. Joseph Kerr Weaver, Norristown; John B. Lober, Philadelphia; John P. Crozier, Upland; Henry F. Walton, Philadelphia, and Dr. U. G. Gifford, London Grove.

Honors to State Board President.—The honorary degree of Doctor of Science was conferred on Dr. Henry Beates, Jr., Philadelphia, for many years president of the board of medical examiners of the state, by Washington and Jefferson College.——At a meeting of the board of medical examiners, held July 28, at Atlantic City, N. J., resolutions were adopted setting forth the regret with which the board noted the resignation of Dr. Beates, wishing him a long and honorable career and hoping that he may be able to see his high ideals fully realized.

Philadelphia

Bequest.—The will of the late Phoebe Woodward devises that $5,000 be placed in trust and the income paid to a sister during her life and at her death, the principal be given to the Episcopal Hospital for the endowment of a free bed in the name of David and Phoebe Woodward.

Typhoid Outbreak Not Alarming.—Although forty-six cases of typhoid fever were reported to the Health Bureau during the week ended August 5, Dr. Andrew A. Cairns, Philadelphia, chief medical inspector, says that there is no cause for alarm as an increased number of cases is always looked for at this time of year when vacationists return to the city.

Reports on Sane Fourth.—At the meeting of the Citizen's Committee held at City Hall on July 27, it was announced that, as a result of the movement for a Sane Fourth, there were but four cases of tetanus from firecracker injuries this year, none of which was fatal. A resolution was unanimously adopted for a permanent citizens' committee to arrange Independence Day celebrations.

Personal.—The following physicians have sailed for Europe: Drs. John Norman Henry, Frederick P. Henry, John McLernon, Albert C. Sautter, James M. Anders, L. Webster Fox, George E. de Schweinitz and Irwin A. Fries.——Governor Tener has appointed Dr. Edgar F. Smith, Provost of the University of Pennsylvania, representative of Pennsylvania at the International Congress of Applied Chemistry in Washington and New York, September, 1912.

Local Druggists' Association Want Wiley.—At the meeting of the Philadelphia Association of Retail Druggists, held on August 4, a resolution was adopted urging President Taft to retain Dr. Harvey W. Wiley, chief chemist of the United States Department of Agriculture, in his present position. During the meeting, Christopher Kock said that another crusade would be started in this city against the sale of opium, morphin and cocain. The State Pharmaceutical Board has been collecting evidence against the alleged sale of the drugs and is following out clues.

RHODE ISLAND

Bequest.—By the will of the late Oliver Henry Arnold, Providence, Brown University received a bequest of $85,000.

Medicolegal Society Organized.—The Medicolegal Society of Rhode Island, composed of lawyers, physicians, coroners and others interested in medical jurisprudence, was organized in Providence, July 20. Judge Benjamin M. Grim, Cranston, was elected president, Hon. Daniel S. Latham, vice-president, and Dr. Carle R. Doten, secretary-treasurer, all of Providence.

District Meeting.—At the annual meeting of the Woonsocket District Medical Society the following officers were elected: President, Dr. William Francis Barry, Woonsocket; vice-president, Dr. Joseph T. Roswell, Woonsocket; secretary, Dr. Joseph Edgar Tanguay, Woonsocket; treasurer, Dr. George R. Smith, Woonsocket; councilor, Dr. John J. Baxter, Woonsocket; delegate to the state society, Dr. James A. King, and censors, Drs. Edgar F. Hamlin, Slatersville, and Joseph H. Boucher and Edward N. Kingsbury, Woonsocket.

SOUTH CAROLINA

Secretaries Elect.—At the annual meeting of the Association of Secretaries of County Medical Societies, Dr. Claude Clinkscales Gambrell, Abbeville, was elected president, and Dr. L. Rosa H. Gantt, Spartanburg, secretary.

Alumni Election.—At the reunion of the graduates of the class of 1901 of the Medical College of the State of South Carolina, Dr. L. Elliott Bull, Cheraw, was elected president; Dr. David M. Michaut, Dillon, vice-president, and Dr. George McFarland Mood, Charleston, secretary-treasurer.

Personal.—Dr. Robert T. Jennings, McCormick, has succeeded Dr. Frank W. P. Butler, resigned, as physician to the state penitentiary, Columbia.——Dr. W. T. Breeland, Allendale, suffered painful injury by being knocked down by his horse, July 23.——Dr. James Adam Hayne, Greenville, has succeeded Dr. Charles Frederick Williams, Columbia, resigned, as State Health Officer and secretary of the State Board of Health.——Dr. Williams has started for Europe.——Drs. Walter Cheyne and Charles P. Osteen have been appointed members of the Sumter Committee on Health and Sanitation.

SOUTH DAKOTA

State Board Elects.—The state medical examining board held its annual meeting at Mitchell last month and elected the following officers: Dr. Frank S. Howe, Deadwood, president; Joseph Mark Walsh, Fort Pierre, vice-president, and Dr. Leslie Grant Hill, Watertown, secretary. The next meeting of the board will be held at Huron in December.

Personal.—Dr. James E. Miller, governor and chief physician of the Battle Mountain Sanitarium, Hot Springs, has been appointed inspector-general of the National Homes for Disabled Volunteer Soldiers and also of the various state homes.——Dr. E. E. Carle, Roseland, has been operated on recently for injuries sustained in an automobile accident and is believed to be out of danger.

TENNESSEE

Society Reorganized.—The Henderson County Medical Society was reorganized recently at Lexington and the following officers were elected: president, Dr. William B. Keeton, Scott's Hill; vice-presidents, Drs. S. T. Parker, Lexington, and Elmer E. Waller, Juno, and secretary-treasurer, Dr. William F. Huntsman, Juno.

Milk Dispensary Opened.—The Memphis Free Milk Dispensary for Babies was opened August 1, at 215 Market Street. Free milk is supplied to babies whose parents are unable to pay for it and to families who are able to pay the milk will be sold practically at cost. The milk used by the dispensary comes from a farm which agrees to furnish milk certified to be standard.

Personal.—Dr. William Krauss, Memphis, has been appointed by the State Board of Health to investigate pellagra in West Tennessee and Dr. J. C. Brooks, Chattanooga, has been placed in charge of this work in East Tennessee.——Dr. Harry D. Miller has succeeded Dr. Daniel Trigg as city physician of Johnson City.——A portrait of Dr. Henry Berlin, Chattanooga, has been presented by a number of women of that city to the Erlanger Hospital.

TEXAS

No Welcome for Lepers.—Dr. Ralph Steiner, Austin, state health officer, has made a supplemental report to the members of the board chosen to select a site for a state home for lepers. He finds that it is impossible to secure a site on account of the opposition and objection everywhere made, and suggests that the thirty lepers in the state might be cared for by the federal government in one of its four or five institutions.

Personal.—Dr. Isaac P. Poyner, Palestine, has been seriously ill as the result of an overdose of headache powder.——Dr. Christopher C. Rutherford, McDade, was seriously injured by a fall, at the home of his son in Yoakum, July 16.——Dr. John N. Howell, Cisco, suffered a loss of $3,000 by a fire which destroyed his library and surgical instruments, July 7.——Dr. Edward H. Schwob, Yoakum, fractured two ribs and sustained other injuries in a street-car accident in New York City, recently.——A gold-headed cane was presented to Dr. James D. Osborne, Cleburne, retiring president of the State Board of Medical Examiners by his colleagues.——Dr. Marvin B. Grace has been appointed health officer of Seguin.

GENERAL NEWS

Personal.—Dr. Charles E. Ruth, formerly of Keokuk, Iowa, who has been living for three years in Porto Rico on account of his wife's health, announces that she has so far recovered that they will return about October 1 and he will resume practice in town.——The degree of master of arts was recently conferred on Captain Henry D. Thomason, M. C., United States Army, by the Pennsylvania Military College.

Sioux Valley Physicians Hold Meeting.—At the annual meeting of the Sioux Valley Medical Association, held at Sioux Falls, S. Dak., July 20, the following officers were elected: president, Dr. John Edward Garver, Sioux City, Iowa; vice-presidents, Drs. Gilbert Geoffrey Cottam, Sioux Falls, S. Dak., and Charles O. Wright, Luverne, Minn.; secretary, Dr. George Stillman Browning, Sioux City, Iowa, and censors, Drs. Gilbert Geoffrey Cottam, Sioux Falls, S. Dak., Philip Benedict McLaughlin, Sioux City, Iowa, Arthur E. Cook, Randolph, Neb., and Alfred E. Spalding, Luverne, Minn. The next meeting will be held in Sioux City, Iowa.

Meeting of Atlantic Coast Surgeons.—At the seventh annual meeting of the Atlantic Coast Line Surgeons, held in Norfolk, Va., July 25 and 26, more strenuous sanitary rules for railroad trains and railroad stations were recommended to the railway companies on the lines suggested by Surgeon Charles P. Wertenbaker, U. S. P. H. and M.-H. Service, in his paper on "Railroad Sanitation." The following officers were elected: President, Dr. James M. Parrott, Kinston, N. C.; vice-presidents, Drs. John Elliott Boyd, Jacksonville, Fla., and Micollins N. Stow, Jesup, Ga.; secretary-treasurer, Dr. Charles P. Aimer, Charleston, S. C. (reelected), and executive committee, Drs. George G. Thomas, Wilmington, N. C., Southgate Leigh, Norfolk, Va., E. L. Cox, Jacksonville, N. C., William S. Lynch, Scranton, S. C., John M. Spence, Camilla, Ga., and George Abner Hammond, Dothan, Ala.

CANADA

Fire in Insane Hospital.—Eight lives were lost in a fire which partly destroyed one of the main buildings of the Hamilton Hospital for Criminal Insane, near Hamilton, August 1, 1911.

Hospital for Fire Sufferers.—At a joint meeting in Toronto, of the relief committee, appointed to distribute funds to fire sufferers in the Porcupine fire-swept district, it was decided to use $10,000 of the fund to establish a hospital at Cochrane, Ont.

Mural Tablets Unveiled.—Two mural tablets were recently unveiled in the entrance hall of the Western Hospital, Montreal; the one in memory of Dr. Francis Wayland Campbell, dean and professor of medicine in Bishop's College and a member of the staff of Western Hospital in 1876 until his death in 1905, and the other commemorating Dr. William Henry Drummond, the Habitant poet, who was a pupil and fellow professor of Dr. Campbell, and an enthusiastic supporter of the hospital.

Opening of Sanatorium.—The Laurentian Sanatorium for the treatment and control of tuberculosis which was informally opened at Ste. Agathe, Que., in May, was officially opened June 15, in the presence of a large gathering of physicians and others from all parts of the Dominion and the United States. The building as it stands has cost $150,000, of which Mr. D. Lorne McGibbon contributed $50,000 and other members of the Laurentian Society $25,000. Dr. Roddick Byer is medical superintendent of the institution.

LONDON LETTER

(From Our Regular Correspondent)

London, July 22, 1911.

Spiritual Healing

In January, 1909, a subcommittee of the British Medical Association consisting of general practitioners, physicians, neurologists and alienists was appointed to investigate the subject of "spiritual healing." Previously, a meeting of clergy and laymen had asked the Bishop of London to form a central church council in the diocese of London for the consideration of questions connected with healing by spiritual means. This led to the conclusion that the subject was of sufficient importance for consideration by the profession. After a study of some literature on the subject the subcommittee had some difficulty in deciding on a clear definition of the meaning attached to the term "spiritual healing" by those who used it. Accordingly a letter was sent to a number of well-known ecclesiastics, including the Archbishop of Canterbury, the Bishop of London, the Dean of Westminster, the Rev. Percy Dearmer (author of "Body and Soul") and others interested in the subject. These gentlemen were asked to assist in clearing up the confusion which existed in connection with the use of the terms "spiritual healing," "faith healing" and "psychic healing." Many long and detailed replies showing a great wish to assist the subcommittee were received. Nevertheless, it cannot be said that these eminent persons threw much light on the subject. They experienced great difficulty in defining the difference between these terms, and none of their utterances added anything to what is generally known. They largely consisted of commonplaces on the influence of mind on body. The subcommittee found great difficulty in obtaining cases for investigation, as those who had written on the subject would not put them in touch with patients treated. The only cases seen were provided by the Emmanuel Society. Ten patients were examined and the diagnosis verified by reference to the records of previous medical advisers, but opportunities for subsequent examination were given in only three cases. It was found that the *modus operandi* in spiritual healing consists in the laying on of hands and praying by the "healer," in surroundings of a more or less impressive character. After carefully considering the various definitions submitted, the subcommittee found that there is no difference in kind between "spiritual healing," "faith healing," "mental healing" and "psychic healing." All these forms seemed to depend for their effect on mental suggestion. There was no evidence to bear out the contention of "spiritual healers" that they had a special "gift of healing." Although there was abundant evidence of the efficacy of suggestion in many disorders, there was none of any authenticated cure of organic disease. The subcommittee concludes that the benefits of suggestion can be obtained from physicians, whose training enables them to distinguish the conditions amenable to it and that, for the protection of the public, it is best left in their hands and they deprecate any formal cooperation between physicians and the clergy.

Fatal Anthrax Contracted by a Laboratory Attendant

A man, aged 24, laboratory attendant at University College Hospital, complained of pains in his head but continued at work. On the third day he came to Dr. Thiele, lecturer on bacteriology at the college and in charge of the vaccine department, and showed him a little pimple on the right side of the neck. Dr. Thiele thought it was a scratch but next morning he noticed that it had become enlarged to the size of a shilling and seemed to show signs of anthrax which was proved to be the case on bacteriological examination. The whole of the lesion was immediately removed, the temperature fell, and in a day or two the patient seemed to be out of danger, but the temperature again rose and in spite of serum treatment he died on the tenth day. The source of infection must have been some tube which he had touched in cleaning up after the students, who were working on anthrax bacilli. Probably he then scratched his neck. Dr. Thiele could not say how this happened, unless some of the students had carelessly allowed some of the organisms to get on the outside of the tube and failed to report it, so that the tube might at once have been put in the steam sterilizer.

A Safe and Efficient Antirabic Vaccine

Lieutenant-Colonel Sir David Semple of the Indian medical service has established the fact that an efficient antirabic vaccine can be made from the dead virus. In a recent research recorded in the Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India he has shown that animals can be as highly immunized against rabies with a dead as with a living virus. He found that the rabies virus was easily destroyed by heat; a temperature of 50 C. killed a 5 per cent. dilution of fixed virus in fifteen minutes. An 8 per cent. dilution in normal saline was killed by 1 per cent. phenol (carbolic acid) at 37 C. in twenty-four hours. When this fluid is diluted with equal volume of normal saline it becomes a 4 per cent. virus in 0.5 per cent. phenol—a very suitable strength for antirabic treatment and containing sufficient phenol to prevent subsequent contamination. This proved efficient in the protection of dogs, rabbits and monkeys against inoculation of the virus. In some cases the protection was not complete, but in these the animals developed the disease later than controls. In addition to safety, this method possesses the great advantage of convenience over that of using the living virus such as is employed in the Pasteur institutes. This cannot be sent to a distance without the risk of impairing its efficiency. On the other hand, the dead virus can be sent to any place where it is required.

PARIS LETTER

(From Our Regular Correspondent)

Paris, July 21, 1911.

An Interesting Discussion on Spinal Anesthesia

Dr. Forgue, professor of clinical surgery at the Faculté de médecine de Montpellier, recently made a report to the Académie de médecine de Paris on novocain spinal anesthesia. On the basis of 320 patients observed, Dr. Forgue concluded that the procedure deserved to be substituted for general anesthesia in many subdiaphragmatic operations. Strong objections were raised. On July 18, several members of the Académie de médecine spoke on the disadvantages of spinal anesthesia. Professor Reclus, especially, who has been the great promoter of local anesthesia in France, remarked that out of Dr. Forgue's 320 cases two-thirds of the patients might have been operated on after local anesthesia. Moreover, 320 cases formed a very small series on which to base conclusions of such a matter. At least 1,000 or 1,500 cases should be observed, for if Dr. Forgue had had one death in one of his late spinal anesthesias, his statistics would thereby become most unfavorable. It is known that there is hardly one death in two or three thousand cases from general anesthesia. No reliance, therefore, can be placed on a series of less than that number. As for local anesthesia, in 12,000 operations performed by Dr. Reclus and his pupils, there has not been one death. Dr. Reclus asks, moreover, what the effect is on the spinal cord of the patient submitted to spinal anesthesia. Here is an organ, protected by Nature with infinite precautions, into which the most violent poisons are nonchalantly injected. There is all the more reason to protest against this encroachment of spinal on the field of local anesthesia because, with the use of recently discovered chemical substances, such as novocain, epinephrin, local anesthesia now permits operations which formerly were not possible, especially the radical cure of hernias. It may be used even in major operations where general anesthesia is contra-indicated.

Dr. Schwartz, *agrégé* professor at the Faculté de médecine de Paris, was of the same opinion as Dr. Reclus. Spinal anesthesia appeared to him, at best, a method to be used exceptionally. Schwartz had had confidence in it but he renounced it entirely and forever on observing the complications to which it gave rise. His last case was that of a woman who had large lacerations of the perineum with rectocele and cystocele, and who could not be placed under the influence of ether. The case, otherwise, seemed ideal for spinal anesthesia, which Schwartz accordingly used. He injected 0.06 gm. of stovain and 0.002 gm. of strychnin sulphate as low as possible in the inferior extremity of the lumbar region. Operation was performed with extraordinary facility but after the following day paralysis of the legs and the sphincters appeared and four or five days afterward a terrible decubitus acutus against which all measures failed.

The observation of Reclus and Schwartz were supported by Dr. Delorme, medical inspector-general of the army.

Erroneous Information in Regard to the Academy of Medicine

In the *New York Medical Journal*, July 1, 1911, I was surprised to read that "Dr. Léon Labbé, one of the most distinguished surgeons in France, is president of the academy." This information is rather belated, for Dr. Labbé was president of the Académie de medecine in 1909. In 1910, Dr. Dieulafoy was president and this year Professor Lannelongue has passed from the vice-presidency to the presidency, as I mentioned in a previous letter (THE JOURNAL, Jan. 14, 1911, p. 130). It is the rule that the vice-president of one year becomes the president for the following year and the presidency lasts only one year.

Personal

The Académie des Sciences has just elected Professor J. Bernstein of Halle-sur-Saale, as correspondent.

Obligatory Report of Acute Anterior Poliomyelitis (Infantile Paralysis)

On July 11, Dr. Netter, *agrégé* professor at the Faculté de médecine de Paris, read before the Académie de médecine a paper concluding in favor of the addition of acute anterior poliomyelitis to the list of diseases which must be reported. Report should be made, not only on typical cases, but on doubtful cases. This should be done at all times even outside of epidemic periods. Not only convalescents but their brothers and sisters should be excluded from school for three weeks. Objects capable of being soiled by the secretions and excretions of the patient ought to be disinfected in the course of the disease and in the convalescence. The room should be disinfected after recovery. The academy voted in favor of these conclusions.

A Discussion in the Senate on Classical Studies and Medical Instruction

In one of the last sessions of the senate, during the discussion of the budget of the ministry of public instruction, there was an interesting discussion in regard to the utility of classical studies in which several physicians took part. Dr. Léon Labbé especially insisted on the necessity of classical culture to enable one to undertake the study of sciences, medical science in particular. He called to witness the great German chemist Liebig, through whose influence the first "realists" schools (*Realschulen*) were founded in Germany, who later, taught by experience, wrote: "The pupils of the *Realschulen* who come into my laboratory are, during the first year, superior to those of the gymnasia; the second year they are equal to them; the third year they become inferior." Dr. Labbé likewise recalled the incessant demand of the Medical Council of London that more and more stress should be laid on the humanities. He also cited Professor His of Berlin, who devoted his inaugural address of clinical medicine to establish the absolute necessity of a general culture of high order for undertaking medical studies to advantage.

Professor Debierre, who was recently elected senator, likewise considers Latin and Greek as necessary for a physician or lawyer as for a literary man or a man of science. He cites his personal experience, which goes back more than twenty years. As professor of anatomy at the Faculté de médecine de Lille, he took part in the scientific and professional education of several generations of studies under the old and under the new regime. He has been able to observe that medical students having the so-called modern baccalaureate (without Greek or Latin) were less prepared for scientific culture than pupils educated under the old regime. At present, declares Professor Debierre, some pupils of our medical schools do not understand scientific language because they have not learned Greek and Latin.

Rôle of Mercury and Some of Its Salts in Certain Cancers

In one of the last sessions of the Académie des sciences, Dr. Odier called attention to the fact that certain cancer patients who have previously undergone mercurial treatment may retain mercury in their systems for several years. Observations extending over a long period had shown him that nothing was more dangerous for cancer patients than to have them follow antisyphilitic treatment. In view of the irritation produced by mercury in the epithelial cells, Odier asks if mercury and its salts administered copiously and in increasing measure in modern therapeutics do not play an important rôle in the causation of cancer.

International Honor to Sir Patrick Manson

The considerable services rendered by Sir Patrick Manson to the study of tropical diseases are well known. The creation of schools and institutions for the study of these diseases are due to him. A committee has been formed to give an international testimonial in his honor. A subscription has been opened to offer Sir Patrick Manson a gold medal bearing his portrait. This medal will be about 7 cm. high by 5 cm. wide and will be executed by Dr. Paul Richer, member of the Académie des beaux-arts and of the Académie de médecine de Paris and professor of anatomy at the Ecole des beaux-arts.

May Syphilis be Considered an Industrial Accident?

The Paris courts have been called on to decide whether syphilis contracted in the exercise of his profession by a mechanician-dentist constitutes an industrial accident. A mechanician-dentist working for a surgeon-dentist was wounded in the little finger; the patient being syphilitic, the mechanician contracted syphilis. On the ground that his infirmity was permanent and that he had experienced a reduction of 80 per cent. in his professional practice, the mechanician-dentist demanded from his employer an annual income of 2,912 francs. The courts did not accept his point of view on the ground that the profession of dentist was a liberal profession and that the dentist employer was not subject to the law with regard to industrial accidents. In the liberal professions, syphilis cannot, therefore, constitute an industrial accident.

The Chair of the Physiology of Speech in the Sorbonne

M. Marge, a doctor in medicine and science, who has been for eight years giving, at the Faculté des sciences de Paris, a course of biologic physics applied to phonation and audition, has just been appointed to give a course on the physiology of speech. This new chair was connected with the institute of phonetics which will soon be opened.

Danger of Arsenic in Vinegrowing

For some months all vineyards have been devastated by a terrible parasite, the cochylis, against which arsenate of lead has been used. Dr. Cazeneuve, senator of the department of the Rhône, has just addressed to the minister of the interior a letter calling attention to the danger to public health in the unrestrained sale of arsenical compounds, which is contrary to the law. Against the decision unanimously taken by the Académie de médecine and by the Council on Public Hygiene and Salubrity of the Seine, lead arsenate has been sold by thousands of kilos in all the vinegrowing regions, just at the time when the usage of white lead was put under the ban of law. The government has even sent aid under the form of arsenates. Dramatic and sensational accidents, such as were to have been expected, have occurred in several departments, without counting those more numerous cases which escape observation owing to their chronic and insidious character, but which are even more serious and dangerous. According to information furnished Dr. Cazeneuve by competent persons, lead arsenate and the arsenical salts are, moreover, altogether inefficacious against the cochylis. Therefore, Dr. Cazeneuve has just asked the minister to put an end to these dangerous practices which are strictly forbidden in Germany and other countries. It is said that in the south, growers spray not the leaves alone but the bunch of grapes itself with arsenic.

Insufficient Supply of Guinea-Pigs at the Pasteur Institute

The laboratories of the Pasteur Institute use each month more than 2,500 guinea-pigs. There was founded several years ago, therefore, an establishment at Garches, near Paris, for the breeding of these animals, but it produces only about 20,000 guinea-pigs a year, so that the institute is obliged to secure elsewhere about 10,000 guinea-pigs. Since these little animals are very expensive to raise, farmers do not find it profitable to breed them. The price of guinea-pigs varies between 1 fr. 25 and 1 fr. 50 (25 to 30 cents), and they are not easy to procure at that price. Mice and rats used in experimental medicine also have gone up in price. One franc is now paid for a mouse and 1 fr. 50 for a rat. For the maintenance and the purchase of experimental animals the Pasteur Institute spends more than $80,000 (400,000 francs) a year.

The Expenses of the Public Charities

The last report of M. Mirman, director of public charities and hygiene, shows that the number of beneficiaries of medical charity is constantly increasing. The number, including those treated at home and at the hospitals, has increased from 615,871 in 1895 to 996,539 in 1909, a continuous and almost regular increase of 27,000 a year. Expenses have increased still more. From about $739,200 (3,696,000 francs) in 1895, it amounted in 1909 to about $3,483,400 (18,416,000 francs). The number of beneficiaries under the law of 1905 in regard to assistance to the aged, infirm and incurable has not ceased to increase, but is not increasing so rapidly. On March 31, 1911, there were 577,816 beneficiaries under the law.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, July 21, 1911.

Personal

Professor Sahli of Bern has declined the call as successor of Moritz at Strasburg and Professor Wenckebach of Groningen, Holland, has been called. The latter some time ago declined a call to Marburg. His present call to Strasburg is due to the fact that he had been a candidate for the position at Marburg. There seems to be no reason why German investigators of equal worth should not have been given due consideration.

The Medical Profession and the Krankenkassen

As was to be expected, the managers of the Krankenkassen have quickly taken a position with reference to the resolutions adopted at the Aerztetag at Stuttgart. At the session of the Krankenkassen last week the decision was taken to prosecute the fight against the demands of the physicians and especially to work against the free choice of physicians. The president of the local Leipsic Krankenkasse , the largest Krankenkasse of Germany, with great courage announced that in his society, an agreement had been reached on the basis of a free choice of physicians which satisfied the medical interests, and insured to the management their rights. He was hooted down by the majority of the members of the congress. In all the speeches there appeared the desire to regard physicians as workmen and subordinates of the management of the insurance society. According to this expression of the Krankenkassen the continuance of conflict between the two bodies must be expected even under the new insurance law.

Medical Supervision of Educational Institutions

Medical supervision of educational institutions has lately been essentially increased. Every institution heretofore had to be investigated as a rule within a period of five years by the district physician. A new regulation of the department of the interior and of the minister of instruction requires that certain educational institutions shall be subjected to a yearly visit. This provision refers to such institutions as receive wards, orphans, deserted and lost children as well as all orphanages and rescue homes and a part of the institutions for the protection of children. The district presidents and the police are required to furnish the district physician with a list of the institutions that are to be visited annually. The inspectors of schools of a district are to furnish corresponding information with regard to the schools for small children, institutions for the protection of small children, kindergartens and the like.

Civil Responsibility of an Asylum Physician

A decision that will not fail to awaken great interest among the managers of insane asylums has been rendered by the court of a Berlin suburb. A Berlin attorney who was confined against his will for several weeks in an asylum in this district and was released as the result of his own efforts and that of his attorney against the advice of the physician brought suit for damages against all the persons who participated in what he claimed was an illegal imprisonment. The court decided that the demand of the complainant against the director of the institution was justified on the ground that the physician in order to maintain the imprisonment of the lawyer had given a certificate that did not correspond with the facts. Naturally the director of the sanatorium appealed and a second trial will be held in the upper court. If the accused is also convicted here the suits which the directors of insane asylums have heretofore experienced in considerable numbers will be unpleasantly and expensively increased. We do not believe that this will happen.

Prize Offer for Essay on Racial Hygiene

The Berlin Society for Racial Hygiene (*Berliner Gessellschaft für Rassenhygiene*) has offered a prize of $150 (600 marks) for an essay on the following question: Does material and social advancement involve any danger to families from the standpoint of racial hygiene? As an indication of the scope of the subject the following interesting remarks are made:

"The German people have experienced an incomparable advancement in the last decades. This advance has been accompanied by a remarkable increase of the population which has helped to spread the economic influence and establish the political and military position of the nation. During this period the movement of the population of European nations in the direction of reduction of the birth-rate began, and Germany, especially in its large cities, was rapidly drawn into the current. Especially among the well-to-do and educated classes of the cities, but also among the better situated portion of the working people, the sinking of the birth-rate is already very noticeable. This leads to the extinction of desirable families and thus to the loss of valuable inherited talents and faculties from the life of our race. While men were striving for economic advancement, they forgot the true values of life and have 'overcropped' themselves. On the other hand, it is noticeable that cripples, invalids and degenerates are not only supported by charity, as humanity demands, but the way is smoothed for them to marry and reproduce their kind, while worthy people are prevented from propagation by the harder struggle for existence. Meanwhile the army of the incapable is feeding at the expense of the whole body of society in a constantly more threatening manner, demanding a continually growing sacrifice of money and labor for its care. Thus we are threatened with a diminution, not only in the quantity, but also in the quality of the coming generation.

"We are dealing here with a [illegible] of physical and mental constitution which [illegible] to transmit unimpaired and if possible improved to our posterity. This general theme is of the greatest importance to the nation and the race and should be cleared up by special research among families. For the family is the unit, the social cell in which, in thousands and millions of individual processes, changes take place which often are only very imperfectly represented in the large figures of statistics. The extent and cause of this phenomenon has not yet been investigated with desirable exactness. Especially should it be determined to what extent the economic and social environment, the changed position in life, produce conditions which are unconsciously active in affecting the fertility and character of families.

"It is left to the discretion of the authors to determine whether they will treat the subject from a physiologic, genealogic, statistical or other point of view. But the work must unconditionally add new utilizable material which will satisfy scientific criticism and must be presented in a generally intelligible manner."—The jury of award consists of Professor von Gruber, Professor Martius, Dr. Ploetz and the president of the Berlin Society for Racial Hygiene.

German Spas

The largest part—194 out of 312—of the German sea and mineral bathing-places are in Prussia. Germany possesses 216 mineral spas of which 102 are in Prussia; there are in all Germany eighty-eight watering places on the East Sea and twenty-eight on the North Sea. In the period from 1870 to

1885 the number of Prussian spas amounted to 202 with eighteen exporting mineral waters; from 1886 to 1900 the spas had risen to 269 and the exporting springs to twenty.

The increase in number of annual visitors to the watering places is a decisive evidence of their prosperity. There has been a steady increase in the number of patrons at all the springs in the period from 1870 to 1900. The number of visitors at the baths rose in this time from 99,136 to 585,460, an increase of 486,324, or more than 350 per cent. The most marked increase was from 1885 to 1900 in the period of great economic prosperity. The number of visitors at mineral springs rose from 168,639 to 345,999, that of the patrons of the seaside resorts from 118,751 to 239,403. The increase was really greater than appears, for since 1895 transients have not been included in the count as before. The number of the patrons of all the bathing places of Prussia rose in this five-year period from 365,472 to 585,460, or about 60 per cent. The great majority of the patrons are naturally Prussians and other Germans, yet the number of foreigners has increased very greatly in the last three decades; Russia furnished the largest number of foreigners, in 1870, 2,024; in 1900, 10,477. While in 1870 America furnished only 401 persons to the contingent of visitors, in 1900 it was 2,611. The number of baths taken was in 1900 about 200,000 more in the mineral spas than at the seaside resorts. There has been quite a remarkable increase in the export of mineral water; it rose from 4,588,768 casks in 1870 to 69,350,208 casks in 1900.

So far as the expense of baths and traveling and other expenses of the patrons is concerned, it may be assumed that a patient will spend on the average for a course of mineral baths $100 (400 marks), for a stay at one of the North Sea resorts $52.50 (250 marks), or on the East Sea $50 (200 marks). On the basis of this uncertain estimate we may calculate that the 374,555 patients in 1905 at the Prussian mineral springs must have spent $34,955,500 (139,822,000 marks), at the North Sea resorts 124.937 visitors would have contributed $18,117,140 (72,468.560 marks), while at the East Sea resorts $10,279,800 (41,119,200 marks) would have been spent by 205,596 patients, altogether $63,352,440 (253,409.760 marks). The export of Prussian medicinal and table waters brought in altogether $3,990,400 (15,961,600 marks). The entire financial returns for Prussia in 1905 thus amounted to nearly $67,500,000 (269,371,360 marks). By a similar calculation for the entire German watering place industry we obtain for 1905 the complete sum of $94,284,433 (377,137,733 marks). [These spas are under the control of the state, which also receives the profits.]

Reduction of the Birth-Rate in the Large Cities

According to official statistics, the two-child system seems well established in Berlin. In 1880 a third of the births were fourth to sixth children, while in 1906 these constituted only a fifth of all births. Of late years the first and second born are relatively much more numerous. In 1906 not only was the actual number of all births much reduced, but the relation between these figures had changed materially in favor of the first born and second born which together constituted 60 per cent. of all births. The families in which there was only one child had increased by 32 per cent. In regard to the reduction in the entire birth-rate the statistics show that in 1900 there were in the month of January 25.56 births per 1,000 of the average population of Berlin, but in the same month of 1905 there were only 23.48 births, and in 1909 only 22.37. The smallest number of births is in October: in October, 1900, 23.37; in October, 1906, 21.09, and in October, 1909, 20.12. In the other large cities, such as Breslau, Hamburg, Hanover and Essen the reduction in the birth-rate has not been so large.

To Prevent Communication of Disease in Telephone Exchanges

For the prevention of the transmission of disease among telephone operators the following regulations have been adopted: In exchanges and public telephone offices the transmitter and the receiver shall be cleansed daily by wiping with a soft piece of leather moistened with a weak (about 3 per cent.) solution of phenol. In exchanges doing a large business the use of the same head received and transmitter (*Brust-Mikrophon*) by several operators or telephone assistants is to be discontinued. Each operator and each telephone assistant must be furnished with a separate head telephone receiver for her personal use. Telephone operators who are affected with contagious diseases must be excluded from this service until the danger of communicating the disease to their fellow workers is past. In doubtful cases the question of contagiousness must be settled by the attending physician. The instrument last used by the sick operator must be thoroughly cleansed without delay.

Marriages

Passed Assistant Surgeon Frederick Gustavus Abeken, U. S. Navy, to Miss Frieda Charlotte Schultz of Seattle, Wash., in St. Louis, July 22.

George G. Chittenden, M.D., Twisp, Wash., to Miss C. A. Ross of Beloit, Wis., at Wenatchee, Wash., July 6.

Thomas Clark Chalmers, M.D., New York City, to Miss Elizabeth Ducat of Downers Grove, Ill., August 1.

Lieut. Henry Clay Coburn, Jr., M.C., U. S. Army, to Miss Elma Matilda Sitley, at San Francisco, July 18.

Lolita Day Bew, M.D., San Francisco, and Mr. William Joseph Fenton, at San Rafael, Cal., June 10.

William James Shaw, M.D., Rome, Ga., to Miss Mabel Frances Norris of Riverside, Ill., August 2.

Frederick Henning Schluter, M.D., to Miss Mildred Elinor Burr, both of Brooklyn, N. Y., July 29.

John J. Burke, M.D., Green Bay, Wis., to Mrs. Goldie M. Browne of San Francisco, Cal., July 19.

Valentine B. Fischer, M.D., to Miss Helen Mae Waltemeyer, both of Boulder, Colo., July 25.

Bryant Robert Simpson, M.D., Adams, Neb., to Miss Lulu Culver of Milford, Neb., July 20.

Waitman F. Zinn, M.D., Baltimore, to Miss Katherine A. Burgess, at Baltimore, July 26.

Clinton James Miller, M.D., to Miss Zona Estella McNutt, both of Ord, Neb., July 26.

Samuel B. Grimes, M.D., to Miss Bessie Teare, both of Cincinnati, July 19.

John Lewis Newman, M.D., to Miss Emma R. Steph, both of Chicago, July 3.

Deaths

William G. Adair, M.D. Western Pennsylvania Medical College, Pittsburg, 1895; a member of the Medical Society of the State of Pennsylvania; for several years a school director of Allegheny and for three terms a member of the common councils of Allegheny and Pittsburg; for fourteen years surgeon to St. John's Hospital; died in the Presbyterian Hospital, Pittsburg, July 28, from septicemia, due to an operation wound, aged 43.

Francis Augustine Howe, M.D. Harvard Medical School, 1854; a member of the Massachusetts Medical Society, and for two years president of the Essex North District Medical Society; said to have been the oldest practitioner of the state; a member of the consulting board of the Danvers State Hospital; died at his home in Newburyport, July 28, aged 84.

Howard Morrison Church, M.D. McGill University, Montreal, 1896; of Montreal; demonstrator of anatomy in his alma mater; a member of the Canadian Medical Association and Montreal Medical Society; surgeon-major of the second (Montreal) regiment of Canadian Garrison Artillery; died in the Montreal General Hospital, July 31.

Orvir E. Osell, Medical-Chirurgical College of Kansas City, Mo., 1903; formerly assistant to the chair of clinical ophthalmology in the Medical Department of the University of Kansas; physician to the El Tigre Mining Company, near Douglas, Ariz.; died suddenly at his home, July 25, aged 43.

George C. Smith, M.D. Jefferson Medical College, 1876; a member of the Medical Society of the State of New York; secretary of the Delaware County Medical Society and health officer of Delhi; a veteran of the Civil War; died at his home in Delhi, July 25, from nephritis, aged 71.

Oscar Asa Tolle Haruff, M.D. University of Colorado, Boulder, 1903; of Pueblo; a member of the Colorado State Medical Society; formerly a member of the city council; died July 26, from injuries due to a collision between his automobile and a railway train, near Pinon, Colo., aged 36.

Adelmann Brookins Manley, M.D. Rush Medical College, 1883; of Shopiere; a member of the Wisconsin State Medical Society, who was operated on at the Beloit Hospital, July 23, for appendicitis and intestinal obstruction; died in that institution, July 27, aged 61.

John Alfred Warren, M.D. Eclectic Medical Institute, Cincinnati, 1873; a member of the Illinois State Medical Society; a member of the local board of pension examining surgeons at Greenville, and a member of the local board of health; died at his home, July 29, aged 75.

David Harmon Lovejoy, University of Michigan, Ann Arbor, 1865 (license, Philadelphia County, Pa., 1894); a clergyman and for fifteen years chaplain at the Episcopal Hospital, Philadelphia; died at his home in Roslyn, Pa., July 26, from heart disease, aged 72.

Levi N. Smith, M.D. Kentucky School of Medicine, Louisville, 1881 (license, Kentucky, twenty years practice, 1894); formerly of Western, Neb.; for thirty years a practitioner of Clinton, Ky.; died at his home in that place, July 1, from typhoid fever, aged 64.

Franz B. P. Becker-Laurich, M.D. Long Island College Hospital, Brooklyn, 1893; for several years house surgeon to the Smith Infirmary, Staten Island, N. Y.; died at his home in Greenpoint, Long Island, July 27, from endocarditis, aged 51.

Carl W. Kuhn, M.D. New York University, New York City, 1874; for forty years a practitioner of Manhattan, but since 1895 a resident of Brooklyn; died in the German Hospital in that city, January 4, from chronic nephritis, aged 76.

James M. Fowler (license, Illinois, years of practice, 1878); a veteran of the Civil War; at one time superintendent of schools of Williamson County and a member of the legislature; died at his home in Crab Orchard, July 27, aged 65.

William Burd Evans, M.D. Maryland Medical College, Baltimore, 1902; a member of the Philadelphia County Medical Society; died suddenly in the Woman's Homeopathic Hospital, Philadelphia, July 28, from uremia, aged 33.

Ansin E. Murphy, M.D. St. Louis College of Physicians and Surgeons, 1896; formerly physician in the United States Indian Service at the Lemhi Agency, Ida.; was shot and killed in his office at Salmon, Ida., July 28, aged 61.

Harry H. Hughes, M.D. Tulane University, New Orleans, 1892; for several years district surgeon at Jackson, Miss. for the Illinois Central Railroad; died at his home in Jackson, July 21, from anthrax infection, aged 42.

Ashael Ebenezer Darling, M.D. Harvard Medical School, 1872; a member of the American Medical Association; died at his home in East Killingly, Conn., July 30, from carcinoma of the stomach, aged 66.

Jeremiah Linden Curtis, M.D. Dartmouth Medical School, Hanover, N. H., 1888; assistant surgeon U. S. V. during the Spanish-American War; died at his home in East Dixmont, Me., July 19, aged 54.

Joseph Pierre Lavalaye, M.D. Yale University, New Haven, Conn., 1903; of New Haven; died at the Polyclinic Hospital, New York City, July 21, a short time after an operation for appendicitis, aged 38.

John F. Carey, M.D. Jefferson Medical College, 1867; a member of the Wyoming State Medical Society; formerly of Sussex County, Del.; died at his home in Cheyenne, Wyo., July 27, aged 69.

David James L. Lackie, M.D. Detroit College of Medicine, 1905; a member of the American Medical Association; died at his home in Grind Stone City, Mich., August 1, from pernicious anemia, aged 33.

Joseph Elias Hayne, M.D., 1895; a colored physician, writer, preacher and ethnologist; a veteran of the Civil War; died at his home in Brooklyn, N. Y., January 14, from lobar pneumonia, aged 62.

Francis C. Clark, M.D. Starling Medical College, Columbus, O., 1898; a member of the Nebraska State Medical Association; died at his home in Craig, July 19, from disease of the brain, aged 38.

Thomas Benton Keplinger, M.D. University of Iowa, Iowa City, 1895; of Conway, Ia.; died at the home of his wife's father, near Sharpsburg, Ia., July 13, from tuberculosis, aged 49.

William E. La Dow, M.D. Western Reserve University, Cleveland, 1891; for several years a practitioner of Warrensville, O.; died at his home in Harlem, O., July 22, aged 43.

Lewis Clarence Sampson, M.D. Ensworth Medical College, St. Joseph, Mo., 1900; died at his apartment in St. Joseph, July 23, from cirrhosis of the liver, aged 37.

William L. Castleberry, M.D. Medical College of Georgia, Augusta, 1871; died in his apartments in Lincoln, Ala., July 14, from heart disease.

E. W. Johnson, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1876; died at his home in Tulip, Mo., July 7, from diabetes.

Charles Ambrook, M.D. University of Michigan, Ann Arbor, 1870; died suddenly at his home in Boulder, Colo., July 23, aged 71.

Ida Charlotte Barnes, M.D. Womans' Medical College of Pennsylvania, Philadelphia, 1890; a member of the American Medical Association and of the staff of Christ's Hospital, Topeka, Kan.; died at her home in that city, July 21, aged 50.

John Millard (license Tennessee, 1889); for forty years a practitioner of Sullivan County; died at his home near Bluff City, July 20, aged 83.

George B. Jones, M.D. University of Buffalo, N. Y., 1869; died at his home in Jamestown, N. Y., July 25, aged 68.

R. J. Howard (license, Kentucky, thirty-two years' practice), 1893); died at his home in Pryorsburg, July 21, aged 60.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

PHARMACEUTICAL SPECIALTIES

In European countries, particularly Germany, there are discovered each year hundreds of new substances which are proposed for use in medicine. Little scientific work of this kind seems to be done in this country. American pharmaceutical houses are apparently content to devote their energies to the devising of "pharmaceutical specialties." These usually are mere mixtures of well-known medicaments so put up as to be attractive both to the eye and the palate—especially the latter—and provided with names that are either meaningless or, more often, therapeutically suggestive.

The representative of a foreign firm in this country was discussing the relation of the pharmacist to the physician and of the manufacturer to both. While his viewpoint naturally was biased, yet much that he said was true. For instance: "Pharmaceutical concerns should also stick more to the one drug or active principle idea, and not encourage so many combinations. Leave these for the doctor to prescribe and the retail druggist to prepare."

On the multiplicity of pharmaceutical specialties to be found in this country, he said: "One firm puts on the market some decided improvement; then, the next thing, your larger pharmaceutical firms, instead of putting their chemists to work to improve what you have, tell them to get busy and try to make an imitation; the outcome is that within a year you have some dozen preparations of the same kind, but under different names."

Of course, it is a fact that most of the new drugs—usually definite chemical compounds—which come from abroad, are found in the long run to constitute no real advance. On the other hand, a product of substantial value is occasionally produced and foreign industries may be credited with a share in medical progress. The credit accruing to our pharmaceutical manufacturers is discouragingly small; in fact, it is no exaggeration to say that the average American "pharmaceutical specialty" is not only of no benefit to medicine or pharmacy, but is a distinct handicap and detriment to both professions.

LIQUID NITROUS OXID

Report of the Council on Pharmacy and Chemistry

The referee of the Council appointed to report on the composition of liquid nitrous oxid as found on the market and to make recommendations as to its inclusion with New and Nonofficial Remedies, submitted the following report:

The Section on Stomatology, at the 1909 session of the American Medical Association, having recommended the inclusion of Liquid Nitrous Oxid with the U. S. Pharmacopeia, the Council voted to describe this product with New and Nonofficial Remedies until such Pharmacopeial recognition had been secured. This action having been decided on, it was necessary to provide a standard of purity for this substance. Correspondence with those who make liquid nitrous oxid, as well as with those who use it, brought out very little information as to what degree of purity should be required. It therefore became necessary to examine the product as it was found on the market.

Prof. Warren R. Smith of Lewis Institute, Chicago, kindly offered to cooperate with the Council and to make an examination of liquid nitrous oxid. The referee herewith transmits the very thorough report regarding the composition of commercial liquid nitrous oxid which has been made by Professor Smith in collaboration with Edwin D. Leman. The referee recommends that the Council express its appreciation for the work, and that it request publication of the report in THE JOURNAL. The referee further recommends that the description of liquid nitrous oxid submitted herewith be adopted for inclusion with New and Nonofficial Remedies.

This report was adopted by the Council, and in accordance therewith the examination of Smith and Leman is published below, and the description of liquid nitrous oxid appears with New and Nonofficial Remedies on another page of this issue of THE JOURNAL. The increasing use of nitrous oxid gas, not only as the sole anesthetic in minor operations, but as a preliminary to ether or chloroform anesthesia, makes the adoption of a standard of purity for this substance highly desirable. W. A. PUCKNER, Secretary.

The Purity of Nitrous Oxid

PROF. WARREN R. SMITH AND EDWIN D. LEMAN

Nitrous oxid is commonly sold in cylinders containing 25 ounces of the liquid, which is approximately equal to 100 gallons of the gas under ordinary conditions. We have analyzed four cylinders of this material from different makers. Three of these samples were purchased in the open market, and the other was supplied to us through the courtesy of the dealer. We find that all these samples contain nitrogen as the principal impurity, that two of them contain oxygen and that one contains oxygen and carbon dioxid.

All samples were tested qualitatively by passing from 2 to 4 liters of the gas through solutions of barium hydroxid, litmus, silver nitrate, potassium iodid and starch and Nessler's reagent, with negative results in every case except the one which showed carbon dioxid. These results proved that the samples were free from acids, chlorin, the higher oxids of nitrogen, ammonia and various other less probable impurities. The findings in the quantitative analysis are given below.

These results cannot be taken as representing the contents of the cylinders with the same degree of exactness than can be obtained in the analysis of other materials of different nature, because, aside from the ordinary difficulties in the analysis of a gaseous mixture, the problem is complicated by the fact that the impurities (oxygen and nitrogen) are apparently held in solution in the liquid nitrous oxid and as the gas is drawn off, they tend to escape from the solution at a more rapid rate, proportionally, than the nitrous oxid. The result is that the first portions of gas drawn from the cylinders are much more impure than the later portions. From a product containing originally 96.1 per cent. of nitrous oxid, samples varying as widely as from 87.2 per cent. to 98.5 per cent. have been obtained. The greater part of the nitrogen escapes with the first half of the gas, but the oxygen and a small part of the nitrogen persist throughout.

This possibility of variation in the composition of the gas as drawn from the cylinders should be known and reckoned with in the administration of the gas. It seems, also, to make a difference whether the sample of gas drawn for analysis is that which has been standing for some time in contact with the liquid, or is that which comes from the liquid after the gas in the upper part of the cylinder has been drawn off. This variation complicates the analysis, but is hardly enough to be of significance in the administration of the gas. The results given below are either averages of those obtained from samples drawn at intervals during the escape of the entire quantity of gas from the cylinder or of material drawn directly from the liquid itself, methods which we have proved to give results practically identical.

Percentage of	No. 1.*	No. 2.*	No. 3.*	No. 4.*
Nitrous oxid........	95.4	93.4	95.8	96.1
Oxygen	0.0	1.4	1.1	00.1
Nitrogen	4.6	5.2	3.1	3.5
Carbon dioxid.......	0.0	0.0	0.0	0.3

* 1 = Johnson & Lund; 2 = Ohio Chemical and Mfg. Co.; 3 = The Lennox Chemical Co.; 4 = S. S. White Dental Mfg. Co.

Carbon dioxid was determined by absorption with alkali, oxygen with alkaline pyrogallol, nitrous oxid by explosion with hydrogen and nitrogen by difference.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

TYPHOID VACCINE AND THE WIDAL TEST

To the Editor:—In Major Russell's report to Congress, "The Control of Typhoid in the Army by Vaccination," he states that following the use of typhoid vaccines the blood of the individual treated shows the Widal reaction in very great dilutions. Is this a good test to determine whether the vaccination has "taken" or not? If the blood does not show a positive Widal about four days after the administration of the last dose of vaccine does this mean that immunization did not take place? This has been my experience in using Mulford's vaccine. A. MAVERICK, San Antonio, Texas.

ANSWER.—In Circular 4, issued by the surgeon-general, giving directions for the administration of the typhoid prophylactic, the following statement is made: "The Widal reaction is always positive after typhoid prophylaxis; it appears in about ten days after the first dose and remains positive for six months to a year. This must be considered in diagnosing typhoid in immunized persons; they give a positive Widal regardless of the nature of the illness, and the reaction is consequently of no assistance in making a diagnosis. If typhoid is suspected the diagnosis should be confirmed by blood-culture." The strength of the Widal is increased after the second and third dose and it does not begin to fall off until about ten days after the last dose. If the blood-serum does not give a positive Widal after the administration of the prophylactic the inference is plain that the person has not been immunized and the failure in such a case is most probably due to the use of an inert vaccine.

AN AMBIGUOUS STRYCHNIN PRESCRIPTION

To the Editor:—Will you kindly tell me how to put up this combination?

Strychninæ sulphatis	gr. i
Hydrastinæ hydrochloridi	gr. x
Solutionis acidi borici saturatæ gtts..	cccc

P. J. B. L.

ANSWER.—Inasmuch as the size of a "drop" is variable (depending on the nature of the orifice from which the liquid falls) the prescription is ambiguous. Although under ordinary conditions a "drop" measures usually less than a minim; the prescription was put up by our chemists in the proportion of strychnin sulphate, 1 grain; hydrastin hydrochlorid, 10 grains, and saturated solution of boric acid, 400 minims. It was also put up by using 200 minims of the boric acid solution for the same quantities of the alkaloidal salts. In both cases the salts dissolved readily in the boric acid solution to form a permanently clear solution.

NAUHEIM AND SCHOTT TREATMENT

To the Editor:—1. Please give me the names and addresses of several institutions in this country where the Nauheim and Schott baths are given. 2. Please tell me where I can find some literature regarding the Nauheim and Schott treatment for cardiac hypertrophy.
T. J. WALTHALL, San Antonio, Texas.

ANSWER.—1. Except as may be obtained from advertisements, we have no data from which to select a list of such institutions. 2. The following may be consulted:

Thorne: Nauheim Treatment of Heart Diseases, Pub. Chicago Medical Book Co., Honore and Congress Streets, Chicago. Price, $1.
Thorne: The Schott Method, P. Blakiston's Son & Co., 1012 Walnut St., Philadelphia. Price, $2.
Garson: Remedial Gymnastics for Heart Affections, P. B. Hoeber, 69 East Fifty-Ninth Street, New York City. Price, $2.
Franze, P. C.: Success and Failure in Nauheim Cures, *Medical Record*, May 9, 1908.
Wilson, W. L.: Treatment of Chronic Diseases of the Heart by Carbonated Mineral Baths and Auxiliary Exercises, *Jour. Mich. State Med. Soc.*, August, 1908; abstr. in THE JOURNAL, Aug. 29, 1908, p. 784.
Bishop, L. F.: Baths and Exercises in the Treatment of Abnormal Tension of the Heart and Blood-Vessels, *New York State Jour. Med.*, June, 1909; abstr. in THE JOURNAL, Feb. 20, 1909, p. 654.
Bishop, L. F.: Nauheim Methods in Management of Cardiac Disease, *Medical Record*, March 25, 1911.

TREATMENT OF GOITER IN YOUNG GIRLS

To the Editor:—Some time ago I read an article in THE JOURNAL on the treatment of simple goiter or enlargement of the thyroid gland in young girls. Please give me reference to this article.
S

ANSWER.—Probably our correspondent refers to an answer published in this department Oct. 8, 1910, p. 1306. The patient referred to by the inquirer at that time was a young girl, and the answer is appropriate to the question of our correspondent.

QUINZOIN HAIR TONIC

To the Editor:—Can you tell me the approximate composition of "Quinzoin," a so-called hair tonic made by H. S. Peterson & Co., 212 Kinzie Street, Chicago? C. P. Fordyce, Falls City, Neb.

Answer.—The report of an examination of Quinzoin is contained in the *Bulletin of the Kansas State Board of Health,* May, 1910, as follows: "Sample was found to contain 50.4 per cent. of bicarbonate of soda, small quantity of quinin sulphate and approximately 49 per cent. of coarsely ground quassia." Other "prescription fakes" put out by this firm were discussed in The Journal, Dec. 11, 1909, page 2020.

The Public Service

Medical Department, U. S. Army

Changes for the week ended July 29, 1911.

Register, E. C., lieut., left Camp Douglas, Ariz., with troops for Fort McPherson, Ga.

Keefer, Frank R., lieut.-col., left West Point, N. Y., on thirty days' leave.

Rand, I. W., major, left Fort Hancock, N. J., on thirty days' leave of absence.

Hess, Louis T., major, as inspector and instructor, Sanitary Troops, Pennsylvania troops, Indiana, Indiana County, from July 22 to 29, 1911.

Darby, Taylor E., first lieut., is ordered for temporary duty at Fort McPherson, Ga., and after expiration of leave granted, to return to Fort Sam Houston, Tex., until time to depart for the Philippine Islands.

Tignor, Edwin P., dental surgeon, is granted leave of absence for one month effective about Aug. 1, 1911.

Maguire, Daniel F., first lieut., is ordered from Fort. D. A. Russell, Wyo., to Fort Barrancas, Fla., for duty.

Mount, James R., first lieut., is relieved from further temporary duty at Medical Supply Depot, St. Louis, Mo., and will return to Fort Sheridan, Ill.

Kefauver, Lloyd, A., first lieut., is ordered to proceed from Ft. D. A. Russell, Wyo., to Fort Riley, Kan., for duty.

Brown, Polk D., M.R.C., so much of paragraph 16, Special Orders No. 10, Jan. 13, 1911, War Department, as relates to Lieut. P. D. Brown, M.R.C., is revoked, and by direction of the President, he is honorably discharged from the service of the United States, his services being no longer required, after expiration of leave of absence.

Mount, James R., first lieut., is relieved from duty at Fort Riley, Kan., and will return to proper station, Fort Sheridan, Ill.

Poust, Luther R., M.R.C., relieved from temporary duty at Fort Hamilton, N. Y., and will proceed to Fort DuPont, Del., for temporary duty.

Skelton, Robert, M.R.C., relieved from temporary duty with troops at New York State Rifle Range, and will proceed via Fort Jay, N. Y., to his proper station, Fort Adams, R. I.

Chambers, William H., dental surgeon, reported for duty at Army General Hospital, San Francisco, Cal.

Michie, H. C., Jr., lieut., reported for duty at Fort Missoula, Mont.

Denton, William, lieut., reported for duty at Fort Sam Houston, Tex., from Maneuver Division.

Flynn, Thomas J., lieut., reports for duty at Fort Snelling, Minn., from duty at San Antonio, Tex.

Kefauver, L. A., lieut., reported for duty at Fort Riley, Kan., from San Antonio, Tex.

French, W. H., lieut., reported for duty at Fort Hancock, N. J., from San Antonio, Tex.

Mason, George L., dental surgeon, left Fort Snelling, en route to Fort Leavenworth, Kan., for temporary duty.

Creighton, S. S., lieut., reported for duty at Walter Reed General Hospital, D. C., from San Antonio, Tex.

Clayton, Geo. R., M.R.C., left Fort Sheridan, Ill., with troops for duty at encampment of Organized Militia, Chicago, Ill.

Mudd, Leo C., lieut., reported for duty at Washington Barracks, D. C., from San Antonio, Tex.

Jackson, Thomas W., M.R.C., is granted leave of absence for two months on surgeon's certificate of disability.

Reynolds, Charles R., major, is granted leave of absence for one month and fifteen days, effective Aug. 13, 1911.

Davis, Arthur O., first lieut., is relieved from duty, Maneuver Division, San Antonio, Tex., and will return to proper station, Fort Oglethorpe, Ga., for temporary duty, then after expiration of leave, about September 5, will proceed to Manila, P. I.

Walkup, Joseph O., first lieut., is relieved from duty with the Maneuver Division, San Antonio, Tex., and will proceed to Fort Bayard, New Mexico, for duty.

Divins, George G., lieut., reports arrival at Fort D. A. Russell, Wyo., with Field Hospital and Ambulance Company No. 1 from San Antonio, Tex.

Long, Charles J., dental surgeon, returned to Fort Andrews, Mass., from temporary duty at Fort Ethan Allen, Vt.

Farrow, E. J., M.R.C., left Fort Morgan, Ala., en route to Jackson Barracks, La., for temporary duty.

Poust, Luther R., M.R.C., is relieved from temporary duty at Fort Hamilton, N. Y., and will proceed to Fort Du Pont, Del., for temporary duty, vice Major Hartnett, absent on temporary duty.

Skelton, Robert, M.R.C., is relieved from duty with troops at New York State Rifle Range, and July 20 will proceed via Fort Jay, N. Y., to his proper station, Fort Andrews, R. I.

Ford, Joseph H., major, is assigned as inspector and instructor Organized Militia, New Jersey, at Sea Girt, August 5-12, of Sanitary Troops; and on completion, return to station.

Rutherford, Henry H., major, is detailed for the service assigned Major Hess, as inspector and instructor, Organized Militia, Indiana, Pennsylvania, July 22-29. On completion, return to station.

Brown, Polk D., M.R.C., is granted an extension of twenty days to the leave of absence granted him in Special Order 142, June 22, Department of Texas.

Ford, Clyde S., major, granted leave of absence for one month about Aug. 22, 1911.

Reddy, John R., lieut., reports for duty at Fort Jay, N. Y.

Siner, Joseph L., lieut., reports for duty, Fort Ethan Allen, Vt., from San Antonio, Tex.

Crabtree, George H., major, left Culebra, Canal Zone, en route to the United States, on leave of absence.

Bradley, John R., M.R.C., relieved from duty, Fort Leavenworth, Kan., and from present duty, Department of Texas, and from San Francisco, will proceed to P. I. Sept. 5, 1911.

Campbell, George F., M.R.C., ordered to his home when not needed, Department of Texas, and is relieved from active duty, M.R.C., on expiration of two months' leave of absence herewith granted, effective on arrival home.

Bernheim, Julien R., dental surgeon, is ordered to attend meeting of National Dental Association, at Cleveland, Ohio, July 25-28, as representative of the Dental Corps of the Army.

Manly, Clarence J., major, is relieved from duty with Maneuver Division, San Antonio, Texas, and will return to proper station, Fort Douglas, Utah.

Burnside, F. R., lieut., reported for duty at Fort Riley, Kan., from San Antonio, Tex.

Holland, J. H., lieut., reported for duty at Fort Douglas, Utah, from San Antonio, Tex.

Maguire, Daniel F., lieut., reported for duty at Fort Barrancas, Fla., from San Antonio, Texas.

Mason, George L., dental surgeon, is ordered from Fort Snelling, Minn., to Fort Leavenworth, Kan., for temporary duty, 13th Infantry, and to return to station on completion of this duty.

Aydelotte, John T., first lieut., is detailed inspector instructor of the Organized Militia, Texas, at Camp Mabry, Austin, Texas, Aug. 7 to 16, 1911.

Pinkston, Omar W., captain, granted three months' leave of absence, when he can be spared, with one month extension if desired.

Fauntleroy, Powell C., major, is ordered to Camp Perry, Ohio, to duty as surgeon at National Matches.

Appel, Daniel M., colonel, is granted leave of absence for one month, with permission to apply for extension of one month.

Harmon, Daniel W., first lieut., after his arrival at Seattle, Wash., and on the expiration of leave of absence granted him, will proceed to Fort Oglethorpe, Ga., for duty.

Metcalf, Raymond F., captain, ordered to report Sept. 4, 1911, to Lieut.-Col James D. Glennan, Medical Corps, President of the Examining Board, at the General Hospital, San Francisco, Cal., for examination for promotion.

Mason, George L., dental surgeon, reports for temporary duty at Fort Leavenworth, Kan.

Gunckel, George I., dental surgeon, reports for temporary duty at Key West Barracks, Fla.

Beery, H. R., lieut., left San Antonio, Tex., en route to station Fort Benjamin Harrison, Ind.; reported at for duty July 25, 1911.

Darby, T. E., lieut., left San Antonio, Tex., en route to Fort McPherson, Ga.

Eckels, Lauren S., lieut., reports for duty at Ft. McKinley, Me., from duty at San Antonio, Tex.

Robinson, James L., lieut., reports for duty at Ft. Wayne, Mich., from San Antonio, Tex.

McBrayer, Charles E., lieut., reports for duty at Fort Howard, Md., from San Antonio, Tex.

Trinder, John H., M.R.C., left Ft. Jay, N. Y., en route to Ft. Hunt, Va., for temporary duty.

U. S. Public Health and Marine-Hospital Service

Changes for the week ended Aug. 2, 1911. + + +

White, J. H., surgeon, granted twenty days' leave of absence, without pay, from July 20, 1911.

Gardner, C. H., surgeon, granted one month's leave of absence from Aug. 5, 1911.

Cumming, H. S., surgeon, directed to proceed to Cape Charles City to examine keepers and surfmen of the life-saving service.

Vogel, C. W., P. A. surgeon, granted seven days' leave of absence from Aug. 1, 1911.

Pettyjohn, Joseph, P. A. surgeon, granted one month's leave of absence from July 15, 1911, on account of sickness.

Preble, Paul, asst. surgeon, granted three days' leave of absence from July 24, 1911.

Kolb, L., A. A. surgeon, granted two days' leave of absence, July 5 and July 15, 1911, under paragraph 191, Service Regulations.

Altree, G. H., A. A. surgeon, granted fifteen days' leave of absence from Aug. 3, 1911.

Barclay, James, A. A. surgeon, granted fifteen days' extension of annual leave on account of sickness, from July 5, 1911.

Carter, P. I., A. A. surgeon, granted seven days' leave of absence from July 17, 1911, under paragraph 210, Service Regulations.

Fahey, E. W., A. A. surgeon, granted twenty-one days' leave of absence from July 29, 1911.

Robinson, H. D., A. A. surgeon, granted seven days' leave of absence from July 20, 1911.

Stevenson, J. W., A. A. surgeon, granted sixteen days' leave of absence from July 24, 1911, with pay, and forty-five days, without pay, from Aug. 11, 1911.

Stuart, A. F., A. A. surgeon, granted thirty days' leave of absence from July 25, 1911.

Tappan, J. W., A. A. surgeon, granted twenty days' leave of absence from Aug. 1, 1911.

Townsend, F., A. A. surgeon, granted fourteen days' leave of absence from July 25, 1911.

Wilson, J. G., A. A. surgeon, granted fourteen days' leave of absence from Aug. 5, 1911.

Gahn, H., pharmacist, granted four days' leave of absence from July 24, 1911.

La Grange, J. V., pharmacist, granted thirty days' leave of absence from Aug. 14, 1911.

Spangler, L. C., pharmacist, granted two and one-half days' leave of absence from July 27, 1911

Medical Economics

This Department Embodies the Subjects of Postgraduate Work, Contract Practice, Legislation, Medical Defense, and Other Medicolegal and Economic Questions of Interest to Physicians

A Newspaper Editor on Medical Ethics

The growing interest of newspapers in medical matters is but one of the many indications of the increasing sociological importance of the medical profession and its work. In previous years the press has been wont to regard questions of medical ethics and professional procedure as matters which concerned physicians alone and which were of no special interest to newspapers or their readers. The bearing of professional ethics and conduct on society and the public has become apparent and is causing the more advanced and far-sighted newspaper men of the country to give increasing attention to such questions. Particularly significant in this respect is a recent editorial in the Dallas (Texas) *Morning News* which devotes a full column to a discussion of the report of the committee appointed by the Medical Society of Erie County, N. Y., on division of fees. The comments of the editor are so pertinent and clear-sighted as to entitle them to reproduction in full.

The Medical Society of Erie County, N. Y., of which county Buffalo is the chief city, appointed a committee a few months ago to investigate a charge that surgeons were in the habit of dividing their fees with physicians who brought cases to them. The committee, in its report, sustained the charge; that is, it found that the practice was not only wide-spread in that city, but that it was steadily increasing. It volunteered the further statement, based on inquiries that it had made, that this practice of secret and illicit partnership between surgeons and physicians was more or less general all over the country. Of course the Erie County Medical Association put itself on record as being sternly against this practice, as medical associations would everywhere, since perhaps in every community in the country the reputable largely outnumber the disreputable doctors. It pointed out that, aside from all considerations of professional ethics, the evil of this practice, from the standpoint of the public, is that since the least capable surgeons are the ones who will be most liberal in dividing fees with those physicians who bring them cases, it must result in promoting butchery at the expense of surgery. Another consequence must be, of course, to increase the number of unnecessary surgical operations. One naturally puts large faith in the sincerity of his physician; it is a help the patient gives him in his effort to cure, and when a physician gives advice that, on the face of it, is so unselfish, since he resigns his patient to another, the patient is doubly persuaded that the operation is necessary, even if there be no need of it whatever.

The committee of the Erie County Medical Association made several recommendations as to methods of suppressing this practice. We shall concern ourselves with only one of them, the one which, though slowest in its working, is fundamental and must be the surest. It recommended, if we may express it so, that the doctor mills be made to grind slower. It is hardly, however, an original suggestion, for there has long been a pretty general recognition of the fact that the output of doctors, like the output of lawyers, is annually vastly larger than there is any need of. Some think that it is twice as great as it ought to be. Both professions are everywhere overcrowded. It might be thought that that is the misfortune of those professions only, and that the public has no concern in it; but a moment's reflection will convince any one that this evil of dividing fees, like most if not all other evils that have crept into both these professions, is due fundamentally to the increasing difficulty of making a living in them. Where it is a desperate struggle to earn a bare and precarious existence, human nature succumbs easily to the temptation to stoop to practices that are repugnant even to the sentiments of those who are guilty of them. If there is a large and increasing number of unscrupulous physicians and a larger and more rapidly increasing number of conscienceless lawyers, the fundamental and chief cause of it is that there are more doctors and lawyers than society has any legitimate need of.

If the evil is to be checked at its source, the medical and legal schools must prescribe a longer and more difficult climb for those who aspire to a place in these professions, and the test of proficiency now imposed on those who ask license to practice must be made considerably more rigorous. Than that of medicine there is, of course, no profession that men have a deeper concern in, and unless it is that of journalism, there is none that exercises a greater power for good and evil over society than the legal profession. Surely we have ample reason to require very severe tests of those who are ambitious to exercise the power of these professions. The requirements vary widely in the several states and colleges. The motto of some colleges seems to be "Quickness and Dispatch," and some of them have almost reached the point of making you a doctor or a lawyer "while you wait." Youths seem to be taken in to-day as raw, crude material and sent forth to-morrow as finished product with a "God help you" from the faculty, whereas the larger part of the invocation ought to be made in behalf of society. Perhaps it would be well everywhere to exact a higher degree of academic proficiency as a prerequisite to professional study, and then, of course, a more thorough mastery of the professional studies.

The criticisms of the *News* are well taken. It is perfectly true that the essential factor in the present situation is the existence of too many medical schools and the production each year of too many physicians, or at least of too many half-trained physicians. This fundamental fact has been recognized for years, as the work of the Council on Medical Education will show. The original object for which the Association was organized was the elevation of the standard of medical education and, ultimately, the elevation of the profession thereby. The Association has always labored with this end in view and, during the last seven years, through its Council on Medical Education, has been working definitely and effectively for this purpose.

The *News*, however, overlooks or at least fails to mention the important fact that, no matter how vigorous or intelligent may be the efforts of the medical profession to suppress inefficient medical schools or to prevent uneducated and unqualified men from entering the practice of medicine, its labors will be wholly in vain without the support and hearty cooperation of the public. The regulation of medical colleges and the restriction of the practice of medicine to those who are fit are, ultimately, problems which the public must solve, since they depend entirely on the enactment and enforcement of suitable laws in the various states. But how is the public to be benefited if, in spite of the efforts of the Association and the profession, irresponsible and incompetent persons are allowed to organize and conduct medical schools under the laws of the states without any restriction, or with merely nominal restrictions which are practically ineffective? Yet this is possible in many states to-day. How will the public be benefited if, whenever the Association and the profession succeed in raising the standard for admission to the practice of medicine, cults, sects and unscientific pretenders with practically no knowledge of disease are, under the laws of the states, granted an equal right to practice medicine, on requirements and qualifications far below those required of medical men? How will the public be protected, even if stringent laws for the regulation of the practice of medicine are rigidly enforced, if at the same time osteopaths, chiropractics, neuropaths, vitapaths and all the other herds of "isms" are recognized by law and are given the right to treat the sick, on complying with qualifications of their own making? Yet this is what is occurring in many states. No sooner is a standard for admission to the practice of medicine established than its provisions are at once assailed by a multitude who desire the privileges of physicians, without acquiring the necessary training and knowledge. And when the medical profession protests against such nullification of medical practice acts and insists that there should be but a single standard for admission to the practice of medicine it is denounced as a "medical trust" and as endeavoring to restrict the right to practice medicine to its own members. The qualifications for a license to treat the sick are established by the state and not by physicians. What can we think of a state that recognizes two standards for the same privilege? Yet there is no more justification for the state recognizing two or more standards for physicians than there would be for its recognizing two or more standards for admission to the bar

The division of fees on the part of some physicians (fortunately they are few), the introduction of commercialism into the medical profession and the use of unworthy methods to secure practice are, as the *News* truly says, but incidental phenomena resulting from the admission into the medical profession of unfit and poorly trained men. The duty of restricting the practice of medicine to those who are properly trained and qualified is a duty of the public and not of the medical profession alone. It is essentially a sociological and not a professional question. With the rapid development of modern sanitary methods, it is becoming a most important social problem and one which it is the duty of every citizen, and especially of every newspaper editor, to investigate impartially. If the public can be made to realize its duty and interests, the solution of the question will be greatly advanced. As a means to this end, criticism and discussion in the daily press are of the utmost importance and are highly welcome.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Iowa: Capitol Building, Des Moines, September 19-21. Sec., Dr. Guilford H. Sumner.

Missouri: Kansas City, September 25-27. Sec., Dr. Frank B. Hiller, Jefferson City.

New York: September 26-29. Mr. Harlan H. Horner, Chief of Examinations Division, Department of Education, Albany.

Montana April Report

Dr. William C. Riddell, secretary of the Montana State Board of Medical Examiners, reports the written and oral examination held at Helena, April 4-6, 1911. The number of subjects examined in was 10; total number of questions asked, 50; percentage required to pass, 75. The total number of candidates examined was 28, of whom 20 passed and 8 failed. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Denver and Gross College of Medicine	(1905)	80.7
Northwestern University Medical School	(1908)	76.9
Chicago College of Med. and Surgery	(1908) 75; (1911)	79.3

Book Notices

Criminal Man According to the Classification of Cesare Lombroso. Briefly Summarized by His Daughter, Gina Lombroso Ferrero. With an Introduction by Cesare Lombroso. Cloth. Price, $2. Pp. 322, with 39 illustrations. New York: G. P. Putnam's Sons, 1911.

In this popular volume, one of the Science Series, Lombroso's daughter has summarized her father's work excellently. By temperament and training she is well adapted for such a task, having from early youth been associated with her father in the collaboration of his epoch-making studies on the criminal and his treatment. In the introduction to this book—Lombroso's last literary work—he gives the reader glimpses of the several important steps and incidents which led to his special studies in a comparatively new field. Very early in his career, while a young army surgeon, with much leisure to pursue special work, it occurred to him that in order to study insanity, it was necessary to study the patient, not the disease. He therefore began the use of clinical methods in the study of skulls; he applied measurements and weights, the esthesiometer and the craniometer. Still later he applied similar methods to the study of the criminal, primarily with a view to differentiate the criminal from the lunatic. But he soon stumbled on the idea that the criminal was not so much different from the insane, and he entirely discarded the studies of crime in the abstract and betook himself to direct analytical studies of the criminal compared with normal individuals and the insane.

Lombroso himself attempts to retrace some of the steps which led him to make important deductions. He relates that while at work on his problem, it fell to his lot to make the post-mortem examination of a celebrated criminal, the brigand Vitella, who was carefully examined by him during life. This Italian brigand possessed such extraordinary agility that he had been known to scale steep mountain heights, bearing a sheep on his shoulders. During the examination of this criminal's skull, Lombroso discovered in the middle of the occipital bone—the usual location for an elevation or spine—a depression, which he named the median occipital fossa, a finding analogous with that observed in the inferior animals, especially the rodents. This depression in the skull corresponded with the hypertrophy of the vermis, known in birds as the middle cerebellum.

This was a revelation to Lombroso and it immediately suggested to him the problem of the nature of the criminal—an atavistic being who reproduces in his person the ferocious instincts of primitive humanity and the inferior animals. Thus, says he, were explained anatomically the enormous jaws, high cheek bones, prominent superciliary arches, solitary lines in the palms, extreme size in the orbits, handle-shaped or sessile ears found in criminals, savages and apes, insensibility to pain, extremely acute sight, tattooing, excessive idleness, love of orgies and the irresistible craving for evil for its own sake, the desire not only to extinguish life in the victim, but to mutilate the corpse, tear its flesh and drink its blood. The final key, says Lombroso, was given him by the case of Misdea, a young soldier of about 21, unintelligent, but not vicious. Although subject to epileptic fits, he had served for some years in the army when suddenly, for some trivial cause, he attacked and killed eight of his superior officers and comrades. Having accomplished this horrible deed, he fell into a deep slumber, lasting twelve hours, and on awakening appeared to have no recollection of what had happened. This soldier, while representing the most ferocious type of animal, manifested in addition all the phenomena of epilepsy, which appeared to be hereditary in all the members of his family. It flashed across his mind that many criminal characteristics not attributable to atavism, such as facial asymmetry, cerebral sclerosis, impulsiveness, instantaneousness, the periodicity of criminal acts, the desire of evil for evil's sake, were morbid characteristics common to epilepsy, mingled with others due to atavism.

After retracing the steps that lead to his own achievements in the discovery of the congenital epileptoid criminal, Lombroso does not fail to acknowledge the credit due Enrico Ferri and others, who differed from him in that they maintained that Lombroso's type constitutes only a small number of the entire criminal class, and that the greater number of crimes were committed by the occasional criminal and the criminal by passion. Thus, through the epoch-making studies and the advocacy of numerous reforms by Lombroso, the criminal has received humane consideration, and other workers have still further extended the scope of these early studies, so that the edifice of criminal anthropology, circumscribed at first, has extended its boundaries, embracing the special labors on homicide, political crime, crimes connected with the banking world, crimes by women, etc.

The perusal of this book throws a flood of light on the work of the modern school of criminology, of which Lombroso was the founder and most ardent expounder. We know of no more interesting and instructive summer reading for the physician than this well-written and handy volume affords.

General Medicine. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine, Chicago Clinical School. Volume I, The Practical Medicine Series. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School, and Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Series 1911. Cloth. Price, $1.50. Pp. 405. Chicago: The Year Book Publishers.

The greater portion of this volume of the Year-Book Series is taken up with a review of the literature of tuberculosis and the other acute infections of the lungs, pleura and bronchial tubes, and affections of the heart and blood-circulatory system. Most of the remainder is devoted to the physiology and pathology of the ductless glands, and to certain metabolic diseases, as diabetes, gout, obesity and to nephritis. The section on tuberculosis is comprehensive, covering the pulmonary affection in almost every aspect; it indicates that opinion is crystalizing on certain facts regarding the nature and treatment of this disease, one of them being that the infection is general, with its most destructive local manifestation in the lungs; another that sanatorium treatment is the best. In the section on the circulatory system the anatomy and physiology of the heart and vessels, diagnostic methods, and blood-pressure and its significance are well and interestingly covered. Other sections on immunity, vaccine therapy and on poliomyelitis, giving the status of those subjects during the year, complete a very interesting volume.

Spirochetes. A Review of Recent Work with Some Original Observations. By W. Cecil Bosanquet, M.A., M.D., Fellow of the Royal College of Physicians, London. Paper. Price, $2.50 net. Pp. 152, with 90 illustrations. Philadelphia: W. B. Saunders Co., 1911.

This little book is the outcome of a study by the author of the literature dealing with spirochetes. In the first part an effort is made to establish the features peculiar to the genus and in the second part the separate species that have been described are considered briefly. There is a rather useful bibliography appended. The illustrations are numerous, usually fairly well executed, but there are some poor ones. The following statement (p. 15) needs revision: "It is also asserted that whereas bacteriolysins are thermostable (not destroyed by heat), the corresponding substances which act as spirilla (spirochetes) are thermolabile, thus resembling the hemolysins." It is generally accepted that bacteriolysins and hemolysins are quite similar in constitution and behavior with respect to heat and other influences. The book should prove useful as a guide to the literature on the spirochetes.

A Radiographic Atlas of the Pathologic Changes of Bones and Joints. By Amédée Granger, M.D., Lecturer on Radiology and Electro-physics, New Orleans Polyclinic. Cloth. Price, $6. Pp. 207, with illustrations. New York: A. L. Chatterton Co.

This is a collection of seventy-six half-tone plates from skiagraphs of the bones and joints, with explanatory text. The plates are good, and each one is accompanied by a concise instructive description. The volume will prove useful, for reference and comparison, in the interpretation of skiagraphs of these parts, and is worthy of a place in the library of any one undertaking such work.

PRÉCIS D'ELECTROTHÉRAPIE ET DE RADIOTHÉRAPIE OCULAIRES. Par le Dr. A. Leprince (de Bourges). Paper. Price, 3 fr. 50. Pp. 316, with 33 illustrations: Jules Rousset, 12 Rue Monsieur-le-Prince, 1911.

This monograph is the latest and one of the best works on the subject. It opens with a description of most of the appliances required in the manufacture and employment of an important diagnostic and therapeutic agent. While these instruments are mostly of foreign make, yet they have their American counterparts, so that the reader may easily obtain as good as, and in many instances, a better supply at home. Not only are the faradic, galvanic, static and high-frequency currents described and discussed, but phototherapy and the various kinds of radiotherapy receive extended attention. In the second portion of the work, methods of examining receive due consideration. Finally, in the third division of the work, the use of electricity as a purely therapeutic agent in the treatment of ocular affections is discussed. The text is fairly well illustrated and further elucidated by clinical histories and a description of cases in the practice of the author.

Medicolegal

Licenses Revokable for Pretended Olive-Oil Treatment of Gall-Stones—Allopaths, Etc., as Witnesses Against Different Schools—Unprofessional and Dishonorable Conduct

(Berry vs. State (Tex.), 135 S. W. R. 631)

The Court of Civil Appeals of Texas affirms a judgment revoking the license of the appellant Berry, defendant in the court below, to practice medicine in the state of Texas. It was alleged that he had advertised as a physician and specialist, and especially as being skilled in the treatment and cure of cancers and gall-stones; that he had treated a certain woman for gall-stones, promising to remove them for $40; that he gave medicine composed principally, if not entirely, of olive oil; that she took the medicine, believing that it would cure her, and after taking the same passed from her stomach and intestines a large number of balls, of a green color, from ⅛ to ⅜ of an inch in diameter, which were examined by the defendant and pronounced gall-stones by him, whereas the balls were not gall-stones, as the defendant well knew. It was further alleged that the medicine was given with the knowledge and intent that it would form balls, which after passage could be used for the purpose of deceiving the patient. Other instances of such deception were pleaded, and it was alleged that the defendant knew that his representations were false, that they "were grossly unprofessional and dishonorable and of a character likely to deceive and defraud the public." The court thinks that the facts justified the jury in finding that the defendant was guilty of unprofessional and dishonorable conduct such as was likely to and did deceive and defraud the public.

A point was sought to be made of the fact that the law of 1907, under which this suit was prosecuted, does not define what constitutes "other grossly unprofessional and dishonorable conduct of a character likely to deceive and defraud the public." But in Morse vs. State Board of Medical Examiners, 122 S. W. R. 446, the court said that, "unless it be permissible to use language as general as that involved in the statute under consideration, legislation in many instances could not be so framed as to accomplish all that was desired and afford full protection to the public, because of the impossibility of enumerating in detail every separate and distinct act intended to be prohibited." That language was used in regard to the identical part of the statute attacked by the defendant, and the court adopts it as sound and conclusive, however much it may conflict with the decisions of other states. Human ingenuity could not frame a law that would answer the demands of the decision in the case of Matthews vs. Murphy (Ky.) 63 S. W. R. 785, 54 L. R. A. 415, for it would require that every conceivable unprofessional act should be set out and defined before a license could be revoked for any such act.

The question in this case was whether the defendant had perpetrated a fraud on certain patients by giving them certain medicines that would produce certain substances which he represented to be gall-stones and which were not gall-stones at all, and that such representations were fraudulently made, with the intent to deceive the parties to whom he gave the medicine, and thereby obtain money from them. It did not take the wisdom and lore of an "allopath," the knowledge of a homeopath, the philosophy of an eclectic, or the erudition of an osteopath to fit a man to testify to the chemical elements composing the balls, called by the defendant gall-stones; but any chemist of any school of medicine could testify as to their composition. Any one of any school of medicine, or no school, who had the knowledge, could testify that, if a large quantity of olive oil is given and an alkali is also given, a saponaceous mass will be formed in the stomach and intestines. Any one who had obtained the knowledge could testify to the sizes of the cystic duct and common duct and to the ordinary size of gall-stones, and that an ordinary gall-stone could not pass from the gall-bladder through the duct into the stomach or duodenum. No school or system of medicine can change the human anatomy, but it must perforce be the same in all of them, and "allopaths" could testify to questions of anatomy for or against a member of any other school.

It was useless to discuss the question of the competency of a physician of any one school to testify against a physician of another school as to the mode of treatment of disease, because the testimony failed to show different treatment for gall-stones in different schools, and because the defendant showed that he belonged to no one school but was a member of three or more, and was the graduate of several "allopathic" institutions. He was too much of an "allopath" himself to object to "allopathic" testimony, and the court was left in the dark as to whether he gave "allopathic" or eclectic treatment. But, from the amount of oil and other preparations given the patients, the court is justified, perhaps, in presuming that it was not homeopathic treatment. The defendant did not pretend that the olive oil and tartaric acid treatment was taught by the eclectic or any special school, but that it was recognized and accepted in all schools. The "allopathic" physicians were properly allowed to deny the "soft impeachment."

The defendant testified that he knew that the common duct leading from the gall-bladder was too small to accommodate gall-stones of much size; that very little, if any, olive oil taken into the stomach could possibly get into the gall-bladder; that a gall-stone, if dissolved at all in olive oil, must be soaked in it, and the oil must be heated. His testimony alone was sufficient to justify a jury in finding that his treatment was a fraud and that he knew it, and also knew that the material passed by his patients, which he pronounced gall-stones, were not gall-stones.

The statute of 1907 enumerates three causes for which a license may be denied or revoked, but they are separate and independent of each other, and the court is of the opinion that each subdivision of the section is sufficient in itself to justify a judgment of revocation, if supported by facts.

The terms "unprofessional" or "dishonorable" conduct used in the law of 1907 are qualified and modified by the language "of a character likely to deceive or defraud the public," to distinguish them from acts that are unprofessional or dishonorable under the code of ethics prescribed by the honorable profession of medicine that would not, directly at least, react to the disadvantage of the public, such as not advertising, of not entering into a consultation with an attending physician without his consent, and other acts that go to form and constitute the code of the honorable and upright practitioner of medicine. The law leaves to the medical profession the enforcement of its rules of ethics, and, however conducive they may be to creating and preserving the high standard of one of the most important and honored professions in the world, takes no cognizance of them, and does not seek to enforce them, except in so far as their infraction may infringe on the rights and welfare of the public. But when the unprofessional conduct of the member of the medical profession is of such a character as to deceive or defraud the public, then the law denounces such conduct, and strips the offender of the means which make it possible to impose on the credulous and unwary. Such unprofessional conduct would necessarily be closely allied to crime, because it is defrauding the public, and yet it was never intended to confine such conduct to the kind or class of offense that is denounced by the Criminal Code of Texas. That is provided for in a different subdivision of the statute from the one under which this case was prosecuted. The defendant was charged with dishonorable and unprofessional conduct which was calculated to deceive or defraud the public, and such conduct might not necessarily be a crime against the laws of Texas. The gist of the charge in this case was dishonorable conduct calculated to deceive or defraud the public, and the court very properly confined the attention of the jury to that charge. The case of Morse vs. Medical Examiners does not hold that when such a charge as this is made, proof of a felony or other crime must be made, but merely states that the unprofessional conduct must be similar in nature to a crime, as is any attempt to deceive or defraud the public. It is similar and close akin to swindling, but all the essentials of swindling need not be proved in order to justify a verdict of dishonorable or unprofessional conduct.

MEDICAL SOCIETY OF NORTH CAROLINA

Fifty-Eighth Annual Meeting, held at Charlotte, N. C., June 20-22, 1911

Under the Presidency of Dr. C. M. Van Poole, Salisbury

The Pediatric Aspect of Tuberculosis

Dr. Paul H. Ringer, Asheville, N. C.: The child of to-day is the consumptive of to-morrow, and hence prophylaxis is the key-note of the situation. Etiologically, the best authorities favor the inhalation route of infection, despite the assertions of von Behring and others to the contrary. The connection between tuberculosis and the acute infectious diseases of childhood would seem to rest on the catarrhal inflammation of the mucous membranes occurring in the latter, this inflammation when affecting the membranes of the upper respiratory tract paving the way for infections by inhalation. Symptoms of tuberculosis in the child and infant are notoriously inconstant. This applies more to the pulmonary type of tuberculosis than to the infection of other portions of the body. Physical signs are atypical, râles and partial consolidation, so suspicious in the adult, often clearing up rapidly and completely, while sporadic signs in unusual portions of the chest may determine serious trouble.

Modes of treatment are more sociologic and philanthropic than distinctly medical. The following plans have been attempted with success: 1. Sending children of infected families away to the country for a few weeks or months. Life wholly in the open. Fed bountifully and all occupations are out-of-doors. Thus children in the hazy "pretuberculous" stage, or those mildly infected, are restored to health. 2. Children remaining at home are given interest in garden plots and cultivate the same—keeps them in the open. 3. Day camps; extra nourishment. 4. Open-air school.

Treatment depends on two factors: 1. Fresh air and good food; drugs seldom, if ever. 2. Cooperation on the part of the various educational elements of society, medical, sociologic, philanthropic.

Mortuary Statistics in North Carolina for 1910

Dr. Thomas M. Jordan, Raleigh: There died in 1910 from preventable diseases alone, in North Carolina, 6,500 persons; from whooping-cough, 230; measles, 200; diphtheria, 265; small-pox, 5; typhoid, 1,110; tuberculosis, 4,690. The medical profession should demand of the state measures to prevent tuberculosis like other communicable diseases. It is twenty times as destructive to life as measles, whooping-cough or diphtheria, and nine hundred and forty times as death-producing as small-pox. In a public health way, doctors are acting as to tuberculosis exactly as they did when they regarded tuberculosis as incurable and non-communicable.

DISCUSSION

Dr. C. A. Julian, Thomasville: Physicians should be required to report privately all cases of tuberculosis to their superior health officers, and these officers should be required to furnish such patients with health instructions and make them carry out the instructions in detail. Every case of tuberculosis should be cared for by the state, where the families are unable to care for their own patients. I do not believe in placarding the homes of such patients, because that gives the public a false feeling of fear. Where proper care is had in these homes, and if a private report has been made on these cases, and the law is followed to the letter, and the doctor and the patient do their duty, the patient is not a menace and does not require a card sticking up outside his door advertising the fact that he has tuberculosis.

Treatment of Intestinal Tuberculosis

Dr. Samuel G. Gant, New York: The therapeutic measures employed by me in the treatment of bowel tuberculosis are as follows: (1) Measures for improving the general health. (2) Symptomatic treatment using codein, guaiacol or creosote to allay irritable coughing, opium and belladonna to control pain, cramps and diarrhea and, when necessary, combining them with an antiseptic or astringent. (3) Irrigations of ichthyol, balsam of Peru, boric acid or krameria and soda ½ per cent., alternated daily with high injections of olive oil and bismuth to soothe the bowel. (4) Topical applications of silver nitrate 8 per cent., balsam of Peru or ichthyol, 20 per cent. made directly to the ulcers tri-weekly through the proctoscope or sigmoidoscope. (5) Surgical treatment including appendicostomy and cecostomy by means of which a way is provided for through and through irrigation; exclusion for the purpose of preventing the feces from passing over the affected segment and resection where the diseased intestine is removed, which offers the best permanent results.

The Ileocecal Fold and Chronic Appendicitis

Dr. J. Shelton Horsley, Richmond, Va.: Operations for chronic appendicitis, while practically free from mortality, do not always relieve morbidity. The essential cause of unrelieved pain is the fact that the condition which produced the pain was not corrected. Either the diagnosis was not accurate and such diseases as stone in the kidney, rheumatism, spinal trouble, ulcer of the duodenum or stomach or Lane's kink were not excluded or else the local condition about the appendix was not properly interpreted. The ileocecal fold may be shortened by inflammation and consequently produce a pulling or a kinking of the terminal ileum or it may be so constricted by a ligature on the mesentery of the appendix as to cause a greater pulling by the ileocecal fold than existed before the operation. This fold is inserted in the terminal ileum and the ileocecal junction. If well developed it may cover as much as the last 3 inches of the ileum and passes downward into the border opposite the mesenteric attachment. It passes down and blends with the mesentery of the appendix and sometimes is inserted into the appendix itself. Consequently, a ligature in the mesentery of the appendix will produce a marked pulling on the ileum when the ileocecal fold is well developed. I remove the ileocecal fold, if at all well developed, in every operation for chronic appendicitis. I cut this fold close to its insertion into the ileum and dissect it down to where it reaches the mesentery of the appendix, at which point it is ligated. Since adopting this procedure there have been fewer complaints of postoperative pain from patients operated on for chronic appendicitis.

Acute Pancreatitis: Report of a Case

Dr. R. L. Gibbon, Charlotte: A man, aged 46, had enjoyed excellent health, with the exception of occasional mild attacks of indigestion. In the last six or seven months he had suffered acute colicky pains in the abdomen, usually at night, lasting a few hours, and coming on at intervals of ten days or two weeks. For a long time his general health had not seemed to suffer, except for the last few weeks, when he began to lose some flesh. The attacks bore little, if any, relation to food taken. Last attack began the night of February 17. Pain was more violent than usual. Abdominal wall was rigid. Temperature, 99½ F. Some vomiting, but not marked. No jaundice. Pain was referred to the epigastric region just below the ensiform and to the left side of the abdomen. Examination of appendix and gall-bladder, negative. Two days later patient's condition unimproved. Blood-count at this time showed hemoglobin, 70 per cent.; red cells, 4,000,000; white cells, 15,600; no nucleated reds; no malaria. Kidney tests, negative. Patient had slept very little since beginning of attack. Facial expression, bad. Tender spots on left side of abdomen.

On February 22, abdomen was opened through right rectus muscle, with a view of being accessible to either gall-bladder, stomach or pancreas. On entering the cavity there were abundant signs of pancreatitis. Adhesions to anterior abdominal wall on left side, and to the body and tail of pancreas. Omentum and fat around bowels, especially in vicinity of pancreas, showed whitish patches of fat necrosis. Pancreas was greatly enlarged, tail extending far over to the left, but contrary to usual rule, head of pancreas was not noticeably swollen, which probably accounts for the absence of jaundice. Gall-bladder appeared normal and no stones could be felt. Patient showing indications of collapse, capsule of the pancreas was torn through at one point and drainage tube inserted, abdomen being closed through at one point and drainage tube inserted, abdomen being closed with through and through silkworm gut. For the same reason, and because no gross pathologic condition was found, the gall-bladder was not drained. For several days after operation but little hope of recovery for patient was entertained. Pulse was weak, color bad, and respiration difficult. After a few days there was considerable discharge of a thick, chocolate-colored pus. Drain was kept open as long as possible. Patient made a gradual recovery, and at the present time is attending to his duties, although he has not entirely regained his flesh and strength.

Enemata in Surgical Cases

Dr. R. L. Payne, Norfolk, Va.: It is a mistake to believe a nutritive equilibrium can be maintained by enemata, and patients suffering from stomach and other troubles requiring operation should not have operation delayed while nutritive enemata are given to build them up. Not more than 300 calories can be absorbed in the twenty-four hours from the rectum, or less than one-sixth the amount necessary to maintain life. The only thing certain of absorption from the lower bowel is water, and the study of cases of starvation show that life is almost indefinitely prolonged if water is supplied freely. This is so not only because water makes up so large a percentage of body tissue but especially because no elimination of the poisonous waste of the tissues can go on without a supply of water. It follows that a patient whose life would be sustained for many days by the caloric resultant from the burning of his own tissues, will die quickly when deprived of water, because of auto-intoxication from retention of his own waste products. It is a serious question, are not albuminoids in the large bowel liable to be broken up by putrefactive bacteria into ptomaines that may become serious sources of danger to the patient? In my own practice, when the stomach will not retain food, I depend almost entirely on normal salt solution or 5 per cent solution of glucose, as glucose requires no digestion but passes directly into the liver to be transformed into glycogen and is abundant in heat-giving power. There are conditions of the kidney in which too much sodium chlorid can be given and in these cases plain water may be substituted. Always remember when the need is urgent, one must not risk irritating the rectum by giving so-called nutritive enemata, but depend on water. All enemas, to be retained, must be given in the Trendelenburg posture and this is accomplished by raising the foot of the bed.

2 and 3. Abstracted in The Journal, May 6, 1911, pp. 1354 and 1355.

5. **Catatonia.**—The patient, male, aged 23, had shown some erratic behavior for several months, culminating a few days before Stevens saw him in a frank psychosis. He lay in bed with eyes tightly closed and was so utterly irresponsive to every effort to arouse him, to induce him to speak, to move or to open his eyes, that his family were much alarmed and feared that he was suffering from some severe brain lesion. For several days previous he had expressed delusions to the effect that he was the Christ, and that he would live always. For a few days subsequent to admission to the sanatorium he would take food and would talk a little. Soon, however, he ceased to do either, and during the past eleven months he has not spoken a word save on three or four occasions, and has less than half a dozen times taken any food spontaneously. At the few times when he has been induced to speak, he has indicated that he fully understands all that is said to him. His refusal of food resulted in resorting to tube-feeding, which has been done regularly twice daily for the past eleven months. For a short time after admission he abandoned his first state of inertia, and would walk about the house and grounds. This, however, soon gave place to inactivity, so that he would sit motionless for hours. The cataleptic state now presented, with classical *cerea flexibilities.* With eyes tightly closed and lips so closely compressed that they extended forward like a snout, he remained mute and totally inactive, and would maintain indefinitely any posture in which his body or limbs might be placed, regardless of how awkward, uncomfortable or cramped this might be.

About a month after admission this gave place to that condition which has continued to the present, viz., a rigid tenseness of every muscle in the body under his voluntary control. To stand him up was like ending up a log, and to stand him on his head was rather easier than to stand him on his feet. This was continued unmitigated for seven months. About Jan. 1, 1911, it began to be noticed that the patient rolled in bed occasionally, turning from side to side, never turning over on his face, but rolling squarely on his side each time as far as possible without precipitating himself forward. This, from an occasional thing, quickly increased in frequency of occurrence, until by the middle of the month it reached the point where he rhythmically turned back and forth twelve or fifteen times a minute, and for many hours each day. From this point the frequency, or rapidity of the turns increased, as did the number of hours in which he daily engaged in it, until the fastigium was reached on February 9, when by careful estimate, during sixteen and one-half hours he rolled from one side to the other 48,256 times. For a period of six hours he turned 17,648 times, or an average of 49 times a minute. Repeated comparisons during the remainder of the sixteen and one-half hours indicated the rate of turning to be the same. Not unremarkable was the fact that the rhythm of the turning scarcely varied at all. During the latter part of February and through March and April his average was something like 15,000 turns, or approximately 3 miles of rolling daily. Since May 10 he had rolled much less. About this time he was put out on the porch for the sake of fresh air. Thinking that he was there unobserved, he would frequently remain still for an hour, relaxed and looking about naturally. The moment, however, he realized that he was being watched, he instantly closed his eyes, stiffened himself, and resumed rolling.

12 *New Stain for Bacterial Capsules With Special Reference to Pneumococci. E. C. Rosenow, Chicago.
13 *Problem of Transmission in Typhus. R. M. Wilder, Chicago.

12. **Stain for Bacterial Capsules.**—After much experimentation the following method has been devised by Rosenow: Make a thin smear on a perfectly clean slide or cover-glass. If the exudate, such as sputum, is too thick, add enough distilled water so that the material can be spread evenly by means of a piece of fine tissue or cigarette paper. In case of cultures (blood-agar, serum-glucose-agar or Loeffler's blood-serum being preferable) remove a small amount of the growth from the surface of the medium and at once mix thoroughly with a loopful of serum on the slide and spread by means of tissue paper, or better still, make a rather dense suspension in a few drops of distilled water, and then mix an equal quantity of this suspension with serum. As the smear becomes nearly dry, cover for 10 to 20 seconds with a 5 to 10 per cent. aqueous solution of tannic acid; wash in water and blot; stain with carbol (saturated alcoholic solution gentian violet [Grübler] 1 pt., 5 per cent. phenol in water, 4 pts.) or anilin-gentian-violet one-half to one minute, heat over flame but do not boil; wash in water again; Gram's iodin solution for one-half to one minute; decolorize in alcohol (95 per cent.); stain for from two to ten seconds, depending on the thickness of smears, with saturated alcoholic (60 per cent.) solution of Grübler's eosin; wash in water and blot; finally, clear in xyxol and mount in balsam, or examine directly. (If the organism like *B. mucosus* is Gram-negative it may be stained with Loeffler's or aqueous methylene blue.) In case of sputum in which the cocci are imbedded in a more or less tenacious mucus, the capsules, at times, are not rendered stainable by the above method. In that case Rosenow says it is well to fix and stain simultaneously with the 2 per cent. aqueous tannic acid, 4 parts, and saturated solution of gentian violet, 1 part. This modification often gives beautiful results. The cocci, however, decolorize easily and the tannic-acid-gentian-violet may be followed by carbol-gentian-violet and then the usual procedure. Ordinary carbol fuchsin diluted 5 to 10 times, aqueous eosin (50 per cent. sat. sol.) may also be used to stain the capsule although the saturated alcoholic (60 per cent.) eosin has given the best results. Decolorization after the modified Gram procedure of tannic-acid-fixed smears is more rapid than in the case of heat-fixed smears, which should be borne in mind.

13. **Transmission in Typhus.**—That typhus is an insect-borne disease, and that it is contagious only in so far as infected vermin are transmitted from host to host by contact and is not contagious under conditions in which vermin are excluded, appears from Wilder's experimental studies and investigations. He says that three insects should be regarded with suspicion as possible conveyors of the infection. These are the flea, the bedbug and the louse. The epidemiology of typhus indicates the possibility that neither fleas nor bedbugs ordinarily play any great rôle in transmission. The body louse (*Pediculus vestimenti*) stands incriminated, first, by the experimental results of the author and others, and again by the epidemiology of the disease. The louse theory is in every way consistent with the etiology of Mexican typhus so far as this is understood and explains several important phases of the epidemiology which were formerly obscure. Chief among these are, (a) the geographic limitation of typhus to the central tableland of Mexico, (b) the seasonal variation of the disease, and the effect of temperature and rain on the epidemics in Mexico City. It is very important that prophylactic sanitary measures directed against typhus fever should take into primary consideration the body louse.

18. **Hemostasis in Brain Operations.**—One of the chief objects of concern in intracranial surgery should be the avoidance of any unnecessary loss of blood, for at best, in many cases of brain tumor associated with venous stasis, bleeding is likely to be so excessive as to necessitate postponement of the final steps of the procedure until a second or even a third session. The common methods of blood-stilling by sponge, clamp and ligature are largely inapplicable to intracranial surgery, particularly in the presence of bleeding from the nervous tissues themselves, and any device which serves as an aid to hemostasis in these difficult operations will bring a larger number of them to a safe termination at a single sitting, with less loss of blood and less damage to the brain itself. In addition to the more familiar tourniquet for the scalp, and wax for diploetic and emissary bleeding, suggestions are offered by Cushing as to the use of gauze pledgets, dry sterile cotton, fragments of raw muscles and other tissues, as well as sections of organizing blood-clots for superficial meningeal bleeding, and silver "clips" for inaccessible individual points either in dura or brain.

20. **Occlusion of Aorta with Metal Band.**—From observations made in two cases Gatch concludes that the presence of the large waxy casts in the urine in both was due to the diminished blood-supply to the kidneys, brought about by the constriction of the aorta; in the second case this constriction was just above the renal arteries, but in the other, first of the thoracic aorta, and then of the abdominal aorta below the origin of the inferior mesenteric artery. The necropsy findings in the second case, in which the right renal vein was enormously distended, lend some support to this supposition. In this case the constant presence of the casts in the urine, even after the restoration of the normal blood-supply to the organs below the band, is attributed to the obstruction to the vessels of the right kidney. This kidney at necropsy showed marked degenerative changes. Gatch found that the pain of an abdominal aneurysm may be greatly lessened and its growth checked by the application of a partially occluding metallic band to the aorta, proximal to the aneurysm. When the aneurysm is saccular and gives origin to no important vessels a cure is possible by this means.

22. **Carcinoma Mastitoides.**—Morphologically carcinoma mastitoides does not differ from certain forms of carcinoma simplex; the marked difference which does exist is due entirely to the interaction of the carcinoma and the profound inflammatory reaction produced by it. It follows, then, in Schumann's opinion, that this excessive reaction of these special cancer cells on the surrounding tissues, a reaction sufficiently marked to engender a general, diffuse, round-cell infiltrate and connective-tissue hyperplasia so profound as to frequently eventuate in breakdown and abscess formation, must be based

of indigestion. In the last six or seven months he had suffered acute colicky pains in the abdomen, usually at night, lasting a few hours, and coming on at intervals of ten days or two weeks. For a long time his general health had not seemed to suffer, except for the last few weeks, when he began to lose some flesh. The attacks bore little, if any, relation to food taken. Last attack began the night of February 17. Pain was more violent than usual. Abdominal wall was rigid. Temperature, 99½ F. Some vomiting, but not marked. No jaundice. Pain was referred to the epigastric region just below the ensiform and to the left side of the abdomen. Examination of appendix and gall-bladder, negative. Two days later patient's condition unimproved. Blood-count at this time showed hemoglobin, 70 per cent.; red cells, 4,000,000; white cells, 15,600; no nucleated reds; no malaria. Kidney tests, negative. Patient had slept very little since beginning of attack. Facial expression, bad. Tender spots on left side of abdomen.

On February 22, abdomen was opened through right rectus muscle, with a view of being accessible to either gall-bladder, stomach or pancreas. On entering the cavity there were abundant signs of pancreatitis. Adhesions to anterior abdominal wall on left side, and to the body and tail of pancreas. Omentum and fat around bowels, especially in vicinity of pancreas, showed whitish patches of fat necrosis. Pancreas was greatly enlarged, tail extending far over to the left, but contrary to usual rule, head of pancreas was not noticeably swollen, which probably accounts for the absence of jaundice. Gall-bladder appeared normal and no stones could be felt. Patient showing indications of collapse, capsule of the pancreas was torn through at one point and drainage tube inserted, abdomen being closed through at one point and drainage tube inserted, abdomen being closed with through and through silkworm gut. For the same reason, and because no gross pathologic condition was found, the gall-bladder was not drained. For several days after operation but little hope of recovery for patient was entertained. Pulse was weak, color bad, and respiration difficult. After a few days there was considerable discharge of a thick, chocolate-colored pus. Drain was kept open as long as possible. Patient made a gradual recovery, and at the present time is attending to his duties, although he has not entirely regained his flesh and strength.

Enemata in Surgical Cases

Dr. R. L. Payne, Norfolk, Va.: It is a mistake to believe a nutritive equilibrium can be maintained by enemata, and patients suffering from stomach and other troubles requiring operation should not have operation delayed while nutritive enemata are given to build them up. Not more than 300 calories can be absorbed in the twenty-four hours from the rectum, or less than one-sixth the amount necessary to maintain life. The only thing certain of absorption from the lower bowel is water, and the study of cases of starvation show that life is almost indefinitely prolonged if water is supplied freely. This is so not only because water makes up so large a percentage of body tissue but especially because no elimination of the poisonous waste of the tissues can go on without a supply of water. It follows that a patient whose life would be sustained for many days by the caloric resultant from the burning of his own tissues, will die quickly when deprived of water, because of auto-intoxication from retention of his own waste products. It is a serious question, are not albuminoids in the large bowel liable to be broken up by putrefactive bacteria into ptomaines that may become serious sources of danger to the patient? In my own practice, when the stomach will not retain food, I depend almost entirely on normal salt solution or 5 per cent solution of glucose, as glucose requires no digestion but passes directly into the liver to be transformed into glycogen and is abundant in heat-giving power. There are conditions of the kidney in which too much sodium chlorid can be given and in these cases plain water may be substituted. Always remember when the need is urgent, one must not risk irritating the rectum by giving so-called nutritive enemata, but depend on water. All enemas, to be retained, must be given in the Trendelenburg posture and this is accomplished by raising the foot of the bed.

2 and 3. Abstracted in The Journal, May 6, 1911, pp. 1354 and 1355.

5. **Catatonia.**—The patient, male, aged 23, had shown some erratic behavior for several months, culminating a few days before Stevens saw him in a frank psychosis. He lay in bed with eyes tightly closed and was so utterly irresponsive to every effort to arouse him, to induce him to speak, to move or to open his eyes, that his family were much alarmed and feared that he was suffering from some severe brain lesion. For several days previous he had expressed delusions to the effect that he was the Christ, and that he would live always. For a few days subsequent to admission to the sanatorium he would take food and would talk a little. Soon, however, he ceased to do either, and during the past eleven months he has not spoken a word save on three or four occasions, and has less than half a dozen times taken any food spontaneously. At the few times when he has been induced to speak, he has indicated that he fully understands all that is said to him. His refusal of food resulted in resorting to tube-feeding, which has been done regularly twice daily for the past eleven months. For a short time after admission he abandoned his first state of inertia, and would walk about the house and grounds. This, however, soon gave place to inactivity, so that he would sit motionless for hours. The cataleptic state now presented, with classical *cerea flexibilitics.* With eyes tightly closed and lips so closely compressed that they extended forward like a snout, he remained mute and totally inactive, and would maintain indefinitely any posture in which his body or limbs might be placed, regardless of how awkward, uncomfortable or cramped this might be.

About a month after admission this gave place to that condition which has continued to the present, viz., a rigid tenseness of every muscle in the body under his voluntary control. To stand him up was like ending up a log, and to stand him on his head was rather easier than to stand him on his feet. This was continued unmitigated for seven months. About Jan. 1, 1911, it began to be noticed that the patient rolled in bed occasionally, turning from side to side, never turning over on his face, but rolling squarely on his side each time as far as possible without precipitating himself forward. This, from an occasional thing, quickly increased in frequency of occurrence, until by the middle of the month it reached the point where he rhythmically turned back and forth twelve or fifteen times a minute, and for many hours each day. From this point the frequency, or rapidity of the turns increased, as did the number of hours in which he daily engaged in it, until the fastigium was reached on February 9, when by careful estimate, during sixteen and one-half hours he rolled from one side to the other 48,256 times. For a period of six hours he turned 17,648 times, or an average of 49 times a minute. Repeated comparisons during the remainder of the sixteen and one-half hours indicated the rate of turning to be the same. Not unremarkable was the fact that the rhythm of the turning scarcely varied at all. During the latter part of February and through March and April his average was something like 15,000 turns, or approximately 3 miles of rolling daily. Since May 10 he had rolled much less. About this time he was put out on the porch for the sake of fresh air. Thinking that he was there unobserved, he would frequently remain still for an hour, relaxed and looking about naturally. The moment, however, he realized that he was being watched, he instantly closed his eyes, stiffened himself, and resumed rolling.

12 *New Stain for Bacterial Capsules With Special Reference to Pneumococci. E. C. Rosenow, Chicago.
13 *Problem of Transmission in Typhus. R. M. Wilder, Chicago.

12. **Stain for Bacterial Capsules.**—After much experimentation the following method has been devised by Rosenow: Make a thin smear on a perfectly clean slide or cover-glass. If the exudate, such as sputum, is too thick, add enough distilled water so that the material can be spread evenly by means of a piece of fine tissue or cigarette paper. In case of cultures (blood-agar, serum-glucose-agar or Loeffler's blood-serum being preferable) remove a small amount of the growth from the surface of the medium and at once mix thoroughly with a loopful of serum on the slide and spread by means of tissue paper, or better still, make a rather dense suspension in a few drops of distilled water, and then mix an equal quantity of this suspension with serum. As the smear becomes nearly dry, cover for 10 to 20 seconds with a 5 to 10 per cent. aqueous solution of tannic acid; wash in water and blot; stain with carbol (saturated alcoholic solution gentian violet [Grübler] 1 pt., 5 per cent. phenol in water, 4 pts.) or anilin-gentian-violet one-half to one minute, heat over flame but do not boil; wash in water again; Gram's iodin solution for one-half to one minute; decolorize in alcohol (95 per cent.); stain for from two to ten seconds, depending on the thickness of smears, with saturated alcoholic (60 per cent.) solution of Grübler's eosin; wash in water and blot; finally, clear in xyxol and mount in balsam, or examine directly. (If the organism like *B. mucosus* is Gram-negative it may be stained with Loeffler's or aqueous methylene blue.) In case of sputum in which the cocci are imbedded in a more or less tenacious mucus, the capsules, at times, are not rendered stainable by the above method. In that case Rosenow says it is well to fix and stain simultaneously with the 2 per cent. aqueous tannic acid, 4 parts, and saturated solution of gentian violet, 1 part. This modification often gives beautiful results. The cocci, however, decolorize easily and the tannic-acid-gentian-violet may be followed by carbol-gentian-violet and then the usual procedure. Ordinary carbol fuchsin diluted 5 to 10 times, aqueous eosin (50 per cent. sat. sol.) may also be used to stain the capsule although the saturated alcoholic (60 per cent.) eosin has given the best results. Decolorization after the modified Gram procedure of tannic-acid-fixed smears is more rapid than in the case of heat-fixed smears, which should be borne in mind.

13. **Transmission in Typhus.**—That typhus is an insect-borne disease, and that it is contagious only in so far as infected vermin are transmitted from host to host by contact and is not contagious under conditions in which vermin are excluded, appears from Wilder's experimental studies and investigations. He says that three insects should be regarded with suspicion as possible conveyors of the infection. These are the flea, the bedbug and the louse. The epidemiology of typhus indicates the possibility that neither fleas nor bedbugs ordinarily play any great rôle in transmission. The body louse (*Pediculus vestimenti*) stands incriminated, first, by the experimental results of the author and others, and again by the epidemiology of the disease. The louse theory is in every way consistent with the etiology of Mexican typhus so far as this is understood and explains several important phases of the epidemiology which were formerly obscure. Chief among these are, (a) the geographic limitation of typhus to the central tableland of Mexico, (b) the seasonal variation of the disease, and the effect of temperature and rain on the epidemics in Mexico City. It is very important that prophylactic sanitary measures directed against typhus fever should take into primary consideration the body louse.

18. **Hemostasis in Brain Operations.**—One of the chief objects of concern in intracranial surgery should be the avoidance of any unnecessary loss of blood, for at best, in many cases of brain tumor associated with venous stasis, bleeding is likely to be so excessive as to necessitate postponement of the final steps of the procedure until a second or even a third session. The common methods of blood-stilling by sponge, clamp and ligature are largely inapplicable to intracranial surgery, particularly in the presence of bleeding from the nervous tissues themselves, and any device which serves as an aid to hemostasis in these difficult operations will bring a larger number of them to a safe termination at a single sitting, with less loss of blood and less damage to the brain itself. In addition to the more familiar tourniquet for the scalp, and wax for diploetic and emissary bleeding, suggestions are offered by Cushing as to the use of gauze pledgets, dry sterile cotton, fragments of raw muscles and other tissues, as well as sections of organizing blood-clots for superficial meningeal bleeding, and silver "clips" for inaccessible individual points either in dura or brain.

20. **Occlusion of Aorta with Metal Band.**—From observations made in two cases Gatch concludes that the presence of the large waxy casts in the urine in both was due to the diminished blood-supply to the kidneys, brought about by the constriction of the aorta; in the second case this constriction was just above the renal arteries, but in the other, first of the thoracic aorta, and then of the abdominal aorta below the origin of the inferior mesenteric artery. The necropsy findings in the second case, in which the right renal vein was enormously distended, lend some support to this supposition. In this case the constant presence of the casts in the urine, even after the restoration of the normal blood-supply to the organs below the band, is attributed to the obstruction to the vessels of the right kidney. This kidney at necropsy showed marked degenerative changes. Gatch found that the pain of an abdominal aneurysm may be greatly lessened and its growth checked by the application of a partially occluding metallic band to the aorta, proximal to the aneurysm. When the aneurysm is saccular and gives origin to no important vessels a cure is possible by this means.

22. **Carcinoma Mastitoides.**—Morphologically carcinoma mastitoides does not differ from certain forms of carcinoma simplex; the marked difference which does exist is due entirely to the interaction of the carcinoma and the profound inflammatory reaction produced by it. It follows, then, in Schumann's opinion, that this excessive reaction of these special cancer cells on the surrounding tissues, a reaction sufficiently marked to engender a general, diffuse, round-cell infiltrate and connective-tissue hyperplasia so profound as to frequently eventuate in breakdown and abscess formation, must be based

either on some peculiar toxin formed by the cells themselves, or on a localized loss of resistance to tumor invasion, existent in the breast itself. Inasmuch as these growths are almost always found in mammæ either in early lactation or the last weeks of pregnancy, when the glands are functionally at the height of their activity, it would seem that this condition is the determining factor. The exact process can only be described conclusively when more complete knowledge of the chemistry, notably the toxin-forming power of carcinoma, is attained. It seems a logical deduction, however, to Schumann, that when the essential elements of the mammary gland are in full activity, fulfilling their excessive and occasional function, the secretion of milk, that they must be exceedingly vulnerable to the action of any foreign toxin, as a result of which action pronounced inflammatory response is a direct sequence. Diagnosis, as has been said, presents the greatest difficulty, and the only scientific procedure is to excise a small portion of the tissue for microscopic examination in all cases of supposed acute mastitis that do not yield to treatment which should ordinarily effect a prompt reduction of the inflammation. He adds one case to eleven already recorded in the literature by various observers.

59. **Changes in Circulation in Aortic Insufficiency.**—By means of a special arrangement MacCallum was able to estimate the work of the ventricle and to study the influence of various factors on it. He found that the tearing of an aortic valve producing an aortic insufficiency causes the heart to perform an extraordinary amount of work, part of which is devoted to the maintenance of nearly a normal rate of flow in the vessels, while the remainder is expended on the forcing out of a quantity of blood which each time regurgitates through the torn valve. This extensive and violent excursion of the ventricle, together with the effect of the regurgitation, produces a very great pulse-pressure with low diastolic pressure and the low tension of the arterial wall allows a great systolic fling which occupies a relatively large part of the height of the pulse curve and thus causes the dicrotic notch to occupy a low position, which is another characteristic of the collapsing pulse. The malnutrition of the heart muscle which follows the severer insufficiencies, may be enough to cause the rapid dilatation of the heart and the death of the animal. In such cases the results are quite different from those in which the heart maintains its activities.

60. Also published in the *Annals of Surgery*, May, 1911, and abstracted in The Journal, June 3, 1911, p. 1684.

62. **Pneumococcus Peritonitis.** — Pneumococcus peritonitis, Stone says, occurs more often in children than in adults, and more often in female than male children. There are two forms: the encapsulated, which exhibits a first period of invasion, a second period of localized abscess formation, and a third of spontaneous rupture of the abscess; and the diffuse form of general peritonitis rapidly fatal unless treated surgically. The symptoms of onset in both forms, varying only in intensity, are abdominal pain, vomiting, fever and diarrhea. Rigidity is not characteristic. The treatment is surgical intervention as soon as possible. The prognosis of the diffuse form is very bad; of the localized form, fairly good. The pus is characteristic, and often sufficient for diagnosis from its macroscopic appearance alone.

64. **Acute Cholecystitis.**—There was nothing unusual about the clinical features of Churchman's case. The patient presented the typical picture of an acute cholecystitis. She had never had typhoid. The illness began two days before admission with chills, fever and a general aching. Delirium appeared that night and the next day there was abdominal pain, at first general, then localized in the right side and radiating to the right shoulder. Nausea and vomiting were present, but there was no jaundice. The physical signs were those of acute cholecystitis. The gall-bladder was not palpable. The liver was slightly enlarged. At the operation straw-colored fluid was found in the peritoneal cavity, cultures from which remained sterile. The appendix was normal, but the gall-bladder was distended and much inflamed. After isolating it with gauze, it was aspirated, but instead of the pus which was expected a fluid, unlike anything previously seen in the gall-bladder, appeared in the barrel of the syringe. It was for a moment uncertain whether what had been supposed to be gall-bladder might not prove to be a cystic growth of the liver. On opening it, however, a large number of bile-stained stones were found and removed. There was neither bile nor

pus in the gall-bladder. The cystic duct was completely blocked by stones. The contents of the distended gall-bladder consisted entirely of a material like that which had been aspirated. The gall-bladder was drained in the usual manner. Convalescence was without event. Three small stones were found in the tube at the first dressing. The discharge from the biliary fistula was at first brownish, later purulent, then thin and mucoid, but it never contained bile. The wound healed to a pin-point opening, through which the limpid mucoid material, characteristic of hydrops, continued to drain.

The sinus persisted, causing the patient almost no inconvenience, but discharging at intervals. After a year had elapsed, she returned to have it closed. At this operation, the gall-bladder contained much clear mucoid fluid (from which no organism could be grown) and a few faceted, pigmented stones. The distended cystic duct contained many gall-stones and communicated with the gall-bladder by an opening so small that the stones could only with great difficulty be delivered into it. The common and hepatic ducts contained no stones. The usual drainage was carried out. Bile appeared in the sinus on the seventh day and soon became profuse. The wound closed promptly and has remained healed. An agar slant was inoculated with some of the material and the *B. typhosus* grew out in pure culture. The patient's Widal reaction was taken and found positive. A chemical analysis of this material showed it to consist largely of soaps of the calcium salts. Some free fatty acids were also present, but no bile pigments.

81. **Postoperative and Postanesthetic Neurasthenias and Psychoses.**—There is not and there cannot well be any reliable evidence as to the frequency with which neurasthenias or other forms of mental disturbance follow operations, since the operating surgeon often knows nothing of their occurrence, many of them not making their appearance until weeks or even months after surgical and anatomic recovery is complete. The surgeon's records, therefore, only show such acute troubles as passing deliriums, temporary confusion, or aberration, such as sometimes appear directly after operations, and which may with probability be referred rather to the anesthetic or to the physical shock than to the operative procedure; some examples of this type are recorded in the accompanying list. Mitchell has made examination of some hundreds of case histories, taken with few exceptions during eight or ten years past. Certain definite forms of neurasthenia and psychasthenia have been omitted from consideration altogether, as those of sexual origin, a few in which it seemed possible that beginning paresis or dementia præcox was at the root of the symptoms, several in which the history was too vague and those in which the patient for any reason was not long enough under observation for the certain establishment of the diagnosis.

Three hundred and forty-four histories remained after these exclusions. These were reviewed, with the aim of discovering how many of them could fairly and reasonably be classed as postoperative or postanesthetic troubles. Total patients examined, 344: women, 220 (or 64 per cent.); men, 124 (or 36 per cent.). Instances of neurasthenic or mental disorders following operation or anesthesia, thirty-one (or 9 per cent. of the total patients examined); women, twenty-nine (or 94 per cent. of the postoperative cases); men, two (or 6 per cent. of the postoperative cases). The operations in these cases varied widely, from the most trifling surgical intervention, such as ocular tenotomy, straightening of the nasal septum or dilatation of the cervix uteri, up to total hysterectomy and ovariotomy. The worst and most persistent examples of nervous disorder have not by any means always followed the most serious operations. No doubt, says Mitchell, as in other neurasthenic conditions, a certain constitutional or temperamental predisposition is required as a precedent, and one cannot make a rule excluding this as one of the causes, as one would in judging of purely traumatic neuroses; but Mitchell tried to exclude from the list those in which there were marked and distinct causes other than operative in addition to the neurasthenic predisposition. Mitchell says that should the question of surgical treatment of a neurasthenic person arise, much more than the ordinary care must be exercised in deciding on operation. Wise practice will choose any other route than a surgical one, however roundabout it may make the journey. The only sufficient reason for an operation in a neurasthenic is that the procedure is one which would be absolutely demanded were the patient in perfect nervous health. The physician and the consulting surgeon must never be deceived into undertaking an operation for the relief of neurasthenic symptoms, unless these symptoms would imperatively require surgical measures in a person not nervous. An operation may relieve neurasthenic symptoms; it will not cure the patient, and there is a good chance that a few months will see her worse than ever, having gained nothing but a new experience, and very likely an exchange of old symptoms for new ones. One should, he says, think twice before advising an operation on a neurasthenic, and having thought twice it will often prove best to think a third time, and then not operate. Above all, the operation should never be recommended with the idea or even the hope that if successful it will cure the neurasthenic. The neurasthenia may be no worse after than before; but most assuredly it will very seldom be cured.

82. **Nitrogen Metabolism in Duodenal Alimentation.**—In the three cases of duodenal alimentation studied by Einhorn and Rosenbloom the absorption of the nitrogen of the food took place to a normal extent. Nitrogenous catabolism, as measured by the quantities of urea and ammonia that were excreted, was normal in degree. All of the patients had a positive nitrogen balance throughout the duodenal feeding periods.

83. **Dilatation Test for Chronic Appendicitis.**—To make this test a colon tube is passed 11 or 12 inches into the rectum and air injected by means of an atomizer bulb. If, as the colon distends, pain and tenderness to finger-point pressure become apparent at McBurney's point, there is appendicitis. Bastedo has compared the test in a number of instances with the Rovsing test and finds this much the more certain; but at times, after moderate dilatation with air, the Rovsing method of forcing the air back into the cecum may be used with advantage. The indication for the test is a suspected chronic or latent appendicitis, or any persistent digestive or abdominal disturbance, in which no cause can be found for the trouble. Six cases reported by Bastedo are said to illustrate the positive findings of the dilatation test. In the use of the test during the last four years he has had no case in which the test was positive and the operation findings negative. But in two out of all of his cases, the negative finding of the test was followed within six months by a typical attack of appendicitis, and the test was, therefore, presumably at fault. With very few exceptions, therefore, the test has proved accurate, and Bastedo believes that it may well serve as a guide to the necessity for operation, particularly in the three classes of cases mentioned, viz., suspected chronic appendicitis, persistent gastro-intestinal or abdominal disturbance of unknown cause, and appendicitis versus ovarian or tubal inflammation.

86. **Purpura Hemorrhagica.**—The interesting and unusual circumstance connected with this case is the fact that there were no evidences of any integumentary lesions until the constitutional symptoms had practically run their course and had almost caused a fatal termination.

90. **Granuloma Pyogenicum.**—Sutton regards it as being very probable that granuloma pyogenicum is the result of a staphylococcic infection of the upper corium, and that the involvement of the superficial structures is not directly concerned in its production. The irritation set up by the bacteria and their products gives rise to excessive cell proliferation, and the resulting granulation tissue is forced upward through the opening in the epidermis through which infection of the deeper tissues originally took place.

91. **Belladonna Poisoning.**—Knowles reviews a number of cases to show that more or less generalized eruptions not only occur from the internal administration of belladonna or its alkaloid, atropin, but also from absorption through the skin of local applications of the same. The skin does not have to be broken or denuded of epidermis for absorption to take place; the symptoms of poisoning, however, develop much sooner if such is the case. The great majority of the cases exhibit an erythematous or scarlatinal type of eruption, which is more frequently found on the face and the upper portion of the body, but in a fair number of cases the outbreak is generalized. Gangrenous, purpuric and eczematous eruptions have been reported. The author describes a unique, or at least a very unusual, type of outbreak. Although in a great many instances severe symptoms of poisoning are present, the eruption may be unaccompanied by other manifestations of drug absorption. Mydriasis is a quite constant phenomenon; in a few cases, however, the pupils were only slightly enlarged, entirely normal, or unilaterally dilated. The prognosis is favorable; only one death occurred in this large series of cases. Belladonna or atropin may produce a local eruption from the local irritant effect.

92. **Examination of the Blood for Bacteria.**—It is stated by Fried and Sophian that bacteria can be found microscopically in the blood of a large majority (97 per cent.) of cases in which their presence has been demonstrated by blood-culture. In a number of the cases (12 in 132, about 9 per cent.) bacteria were demonstrated in the blood, by them, which had been found sterile by means of blood-cultures taken according to the methods now in vogue in the laboratory. Microscopic examination of the blood with all the methods that have so far been used was not of service in cases in which the presence of Gram-negative organisms was suspected.

93. **Digestion in Fever.**—The average reduction of digestion during fever was found by Nichols to range not over 5 to 10 per cent. This falling off is so small as for practical purposes to be almost negligible; indeed, the digestion of animal and mixed food in fever is quite as good as that of vegetable food in health. The belief in a great impairment of digestion in fever, Nichols says, is an idea based on vague impressions and dogmatic assumptions that has come down to us from the dark ages of medicine. The reduction actually shown by exact observations is so small as to dispel any fear, in general, of fever patients being unable to digest and absorb an adequate amount of the nutriment offered them, or to necessitate, on that account, any diminution of the diet.

103 and 104. Abstracted in The Journal, July 15, 1911, p. 244.

105. **Scarlet Fever.**—Having come to the conclusion that the specific organism of scarlet fever would probably be found in the lmyph-nodes of the body, Vipond confined his work entirely to the glandular system. April 14, 1911, he obtained from the body of a child, 4 years of age (who died of scarlet fever), a number of enlarged axillary and inguinal lymph-nodes, from which he obtained the lymph. This lymph, under strict antiseptic conditions was inoculated into a slant of agar, blood-serum and broth. Within a few hours, a mixed growth developed on the different media, part of which proved to be staphylococcus aureus; and part, a raised white growth, which on examination proved to be bacilli. This bacillus, when isolated, proved to be of rapid growth, and grew steadily on different media, including dextrose-agar, glycerin-agar, blood-agar, plain-agar, blood-serum and broth. On dextrose-agar a well-developed growth was observed within twenty-four hours. From five cases a pure culture was obtained, two from inguinal nodes, one from the axillary nodes, and two from anterior, cervical nodes. Two were post-mortem cases. Having obtained the bacillus which he regards as the specific organism of scarlet fever, Vipond decided to inject a broth culture into a monkey, with the hope that the animal would develop scarlet fever. In this he was not disappointed. The bacilli have been inoculated into five monkeys and two rabbits. Typical scarlet fever has developed in all, including rash, enlarged lymph-nodes and desquamation. No suppuration in any one instance took place at the point of inoculation. Streptococci would likely have had this effect. The same bacilli have been recovered from the lymph-nodes in each instance, and further, the typical growth has developed on the different media. Vipond also succeeded in producing typical scarlet fever in a monkey and in a rabbit by direct contagion from monkeys and rabbits suffering from that disease and recovered the same bacillus from the inguinal nodes of these.

114. Resistance of Small-Pox Vaccine.—It appears from the investigations made by the authors that the large majority of the coal tar disinfectants (phenol, cresols and the like) do not destroy the virulence of vaccine virus in ½ per cent. solutions at five hours' exposure, while with this strength and length of time it is probable that these disinfectants would destroy all non-spore-bearing bacteria.

115. Quarantine or Isolation in Scarlet Fever.—From our present knowledge it appears that scarlet fever is a disease that is transmitted by contact and not by fomites; that the scales of desquamation play very little, if any part, in the transmission of contagion, the chief danger lying in the buccal, nasal and aural secretions; and that the release of each case should be decided on its merits. Curtis advises that in all communicable diseases, it is better to remove each patient to a hospital, but should this be impossible, it is better to isolate the patient and allow the other members of the family to continue their regular vocations, educational and otherwise, as long as the isolation is maintained to the satisfaction of the board of health.

122. Meningococcus Endocarditis with Septicemia.—The cases of meningococcus endocarditis studied by Cecil and Soper have brought out the following interesting facts: 1. The meningococcus, in spite of its affinity for the meninges, may at times become lodged on the endocardium, with the production of an acute vegetative endocarditis. In this respect it resembles most of the other pathogenic bacteria, which, while showing a predilection for some particular organ or tissue, may occasionally produce serious lesions in other parts of the body. 2. The symptoms and pathologic anatomy of meningococcus endocarditis correspond to those which characterize malignant endocarditis of streptococcus or pneumococcus origin. 3. Meningococcus endocarditis may or may not be associated with cerebrospinal meningitis. 4. The portal of entry for the organism in meningococcus endocarditis is probably the upper respiratory tract. It is particularly interesting to note that the avenue of infection is the same as that generally accepted as the portal of entry for streptococcus endocarditis on the one hand, and for meningococcus meningitis on the other. 5. The occurrence of primary meningococcus endocarditis with meningococcus septicemia furnishes evidence in favor of a hematogenous mode of infection in epidemic cerebrospinal meningitis.

123. Treatment in Hemoptysis.—Early in the course of hemoptysis, when the breathing has not altered except for an occasional cough, Wiggers says, one is dealing practically with a normal subject, and the object of paramount importance is to promptly reduce the bleeding by such drugs as lower the pressure within the pulmonary circuit. Investigation by Wiggers shows (1) that this cannot be accomplished by vasomotor drugs, such as nitroglycerin or nitrites, and (2) that cardiac depressants, such as chloroform and pituitary extracts, must be resorted to. If hemorrhage has continued until the heart is very rapid and the respirations accelerated, deep and forcible, it is an indication (1) that the heart and blood-vessels no longer react in a typical manner to certain drugs, and (2) that the anemia of the cerebral centers is being felt. During this stage it is important that the blood-supply of the brain be not reduced by the drugs which check hemoptysis. Hence, the drug that combines an ability to elevate systemic arterial pressure and simultaneously to lower that in the pulmonary circuit is the ideal physiologic agent to employ during this stage. In the entire gamut of drugs investigated, pituitary extract is the only one that possesses this fortunate combination of actions.

127. Hemochromatosis.—Three cases are reported by Sprunt. The first case is one of simple hemochromatosis with the complication of tuberculous peritonitis forming a prominent part of the clinical picture. The other two cases are quite typical of the more frequently described form usually designated as bronzed diabetes. In all three cases there were the associated signs of asthenia, enlargement of the liver, and skin pigmentation which served to make the diagnosis clear in the two cases in which diabetes was present. In one case without diabetes, the diagnosis was made more difficult by the presence of the tuberculous peritonitis, but in this case, too, the association of the signs mentioned was considered very suggestive of hemochromatosis. The onset in the first case was rather insidious. It was more abrupt in the other two, the first symptoms being those of diabetes. The duration of the disease in each case after the appearance of the first symptoms was twelve, ten and five months, respectively. In all the cases there was an increase in those pigments present in less degree physiologically. There was a striking accumulation of fine yellow pigment granules in the tubules of the testes and epididymes and in the vas deferens and seminal vesicles in the third case. In each case there was an increase in the connective tissue of the liver, pancreas, lymph-nodes and spleen. In addition, this occurred to a slight extent in the heart muscle in one case and in the prostate and testicles in another. One case suggested a slow deposition of pigment for a comparatively long time, while the picture in the third case gave one the impression of a rapid continuous process.

cases. Briefly, his mode of procedure consists of gastric lavage, dieting and elimination. For several days the patients were put on peptonized milk and milk and soda, and were thereafter given light diet. No hard-and-fast rule was laid down as to the day of treatment on which the patient was advanced to a light or full diet; each case was considered separately and dieted accordingly. The patients were not allowed up until they had been on light diet for two days. A powder containing 1 grain of mercury-with-chalk powder and 3 of sodium bicarbonate was given thrice daily. For chronic constipation, in conjunction with the above powder, Martin found magnesium sulphate in hot water, every second morning the best aperient. If a satisfactory motion was not obtained, then a soap and water enema was given. The septic condition of the mouth (which was present in every case) was treated with a mouth wash of phenol solution 1 in 80, used frequently and always immediately before and immediately after food. The patients were encouraged to drink copiously of milk and soda, weak tea and imperial drink. This treatment was quite successful in the sixteen cases, the average duration of residence in the hospital being seventeen days. One patient was treated in hospital for about ten days with the text-book drugs without improvement. Martin is of the opinion that in hyperemesis gravidarum, as in eclampsia, prophylactic treatment is of prime importance, and recommends the following as the important points: 1. Bowels to be moved at least once per diem. 2. Prevention of oral sepsis. 3. Good plain well-cooked food, daintily served at regular hours. 4. Kidneys and skin to be kept active. 5. Gentle exercise in the open air daily if the weather is at all suitable and a good supply of fresh air night and day.

7. Hypertrophied Papillæ of Morgagni, Causing

used frequently. This condition, accompanied with sleeplessness, lasted for ten days, when the swelling, pain and tenderness gradually subsided, and within fourteen days from the date of injection the patient was able to walk about, and two days later all inconvenience had disappeared. When the area of swelling had lost the tenderness sufficiently to allow of palpation, it was found to be tense, hard, and fairly sharply defined to a circular area of about 18 to 20 cm. in diameter. There was no necrosis. For intravenous injection, the preparation used was antimony sodio tartrate. One-sixth of a grain in normal saline was injected into a vein of the arm. From Nov. 10, 1909, to Feb. 1, 1910, thirteen injections were given with intervals of about four days; on one occasion there was an interval of sixteen days, on another there was an interval of eight days. The thirteenth injection was received at about 11 a. m., Feb. 1, 1910.

About twenty minutes after leaving the laboratory, while on his way home the patient was suddenly seized with nausea and great weakness. He managed to reach his home unaided. Before Camac could reach him he had had a chill and violent abdominal pain. When Camac saw him he was greatly prostrated, complained of intense headache, and had a temperature of 103.6 F. This lasted five or six hours, when it subsided to normal. The blood was negative for trypanosomes. The urine showed great excess of indican, otherwise it was normal. For twelve days the weakness and abdominal distress continued, and on the thirteenth day from the former paroxysm he had, for six hours, a similar but somewhat less severe
ttack. Trypanosomes were not found at the time of this
ond fever, and have been absent on all subsequent exam-
tions. Blood and spinal fluid inoculations into monkeys,
and mice have been attended by negative results. From
9, 1909, to Jan. 31, 1910, the patient took daily by the

136. **Exploratory or Operative Diagnosis.**—Richardson emphasizes that exploratory diagnosis should be restricted in its application to those cases in which certainty of diagnosis is essential to relief, and in which, from lack of surgical remedy, error means disaster or death.

138. **Mobilization of Stiffened Joints.**—The results obtained in three cases reported by Osgood seem to show the usefulness of Baer's membrane in preventing union after complete bony ankylosis.

140. **Soluble Silver Oxid.**—Silver hydroxid is prepared when an alcoholic solution of potassium hydroxid (caustic potash) is added to an alcoholic solution of silver nitrate at a low temperature, about 40 C. Silver oxid is soluble in much distilled water. Schaefer adds silver oxid to pure distilled water, shaking the mixture frequently and thoroughly, after letting it stand for some time, and then percolating it through a wad of asbestos in a percolator. About 1 gm. of silver oxid is soluble in 3 liters of distilled water, forming a perfectly transparent and quite stable solution of silver hydroxid. This solution of silver hydroxid has a strongly metallic taste, and is, like thallium hydroxid, strongly alkaline, and precipitates from many metallic salts the oxids and hydroxids of the respective metals, and decomposes easily a solution of sodium chlorid with the formation of sodium hydroxid (caustic soda) and insoluble silver chlorid. One advantage over the ordinary salts of silver, like that of the nitrate, for instance, Schaefer says, is that this preparation of soluble silver does not contain an acid to form a salt. This form of a silver preparation is suggested to those who have faith in the therapeutic efficacy of silver in its various combinations.

1. **Necessary Influence of Medical Profession in Home, School and State.**—In considering the welfare of youth, Dukes says the physical conditions which are necessary for mental effort, and the modes of securing or thwarting those conditions, have not hitherto received sufficient recognition. The medical and hygienic inquiry insisted on for all children in all classes of schools is related, not merely to the promotion of a sound intellectual state, the easier acquisition of knowledge, the clearer perception of its application, and the gradual appreciation of method, in place of mechanical and unvaried rules, but also bears a definite relation to the moral development of character. So that the medical examination is a valuable asset in the hands of the educator, which should be utilized from the beginning of school life. Dukes would have the medical examiner in possession of the medical history of the previous health of the child, together with all the important items of the family history. For, although the child may be sound, yet he may be vulnerable in some special way from family predisposition or previous illness, and require protective measures. There is one method, and one method only, Dukes says, that would remove many of the unreasonable disabilities in school life—the possession by the educator of a reasonable knowledge of the elements of physiology and hygiene. But, if the teaching of hygiene in schools is to prove serviceable, it must be carried into practice in the daily life at school.

2. **Mechanical Control of Pneumothorax.**—The main features of Davies' hyperatmospheric machine are an air chamber working on the principles of a gasholder and fed from compressed air and oxygen cylinders; the air in this chamber is at a greater pressure than that required in the bronchial tubes, but after it leaves the chamber passes through a governor and the pressure is there regulated to the required amount; it then passes through Alcock's chloroform box, then through a heating chamber, and so into the trachea by an intubation tube. The expired air leaves the trachea again by the exit pipe of the intubation tube and enters the expiratory chamber, where the pressure is again regulated by a weight valve.

4. **Cesarean Section.**—All the mothers recovered in the ten cases in which Purslow operated. The children were all born alive, with one exception. In this case the patient had been in labor many hours, and forceps had been tried unsuccessfully. The child was known to be dead, as the cord was prolapsed and pulseless, and the reason that Cesarean section was done rather than craniotomy was that the head was high above the pelvic brim and the uterus in a state of violent tetanic contraction, which appeared to presage rupture; on examining the uterus after the removal of the child, an extensive effusion of blood under the peritoneum on its right lateral aspect seemed to show that rupture was already taking place, and hysterectomy was performed. Of the children born alive, two died in hospital, one on the day of its birth, and the other, which was probably premature, on the twenty-third day from diarrhea and vomiting. Of the women operated on, five were in labor at the time of operation, and of these, in two cases the membranes were ruptured; the other five were not in labor.

5. **Excessive Vomiting of Pregnancy.**—The efficacy of drugging in hyperemesis gravidarum is doubted by Martin. He prefers dieting because of the good results obtained in sixteen

cases. Briefly, his mode of procedure consists of gastric lavage, dieting and elimination. For several days the patients were put on peptonized milk and milk and soda, and were thereafter given light diet. No hard-and-fast rule was laid down as to the day of treatment on which the patient was advanced to a light or full diet; each case was considered separately and dieted accordingly. The patients were not allowed up until they had been on light diet for two days. A powder containing 1 grain of mercury-with-chalk powder and 3 of sodium bicarbonate was given thrice daily. For chronic constipation, in conjunction with the above powder, Martin found magnesium sulphate in hot water, every second morning the best aperient. If a satisfactory motion was not obtained, then a soap and water enema was given. The septic condition of the mouth (which was present in every case) was treated with a mouth wash of phenol solution 1 in 80, used frequently and always immediately before and immediately after food. The patients were encouraged to drink copiously of milk and soda, weak tea and imperial drink. This treatment was quite successful in the sixteen cases, the average duration of residence in the hospital being seventeen days. One patient was treated in hospital for about ten days with the text-book drugs without improvement. Martin is of the opinion that in hyperemesis gravidarum, as in eclampsia, prophylactic treatment is of prime importance, and recommends the following as the important points: 1. Bowels to be moved at least once per diem. 2. Prevention of oral sepsis. 3. Good plain well-cooked food, daintily served at regular hours. 4. Kidneys and skin to be kept active. 5. Gentle exercise in the open air daily if the weather is at all suitable, and a good supply of fresh air night and day.

7. **Hypertrophied Papillæ of Morgagni Causing Rectal Symptoms.**—The papillæ of Morgagni are situated at the anorectal junction, and though absent in the majority, are yet present in a considerable proportion of individuals. The symptoms attributed by Martin to these hypertrophied papillæ are irritation, pain, sensation of mass in the rectum. He has found cauterization to be the simplest, quickest and most effective method of destroying the papillæ.

8. **Cardiac Failure.**—The first case cited by Wilson showed heart weakness with diminution in the size of the cardiac area from damage to the heart muscle from the toxins or microorganisms of acute rheumatism. In this case the left ventricle was rather weaker than the right, and the latter showed a slight amount of the adolescent type of dilatation and a pulmonary artery murmur. The second case was one of the muscular failure of the heart, without evident dilatation, due to malnutrition presumably from atheroma of the coronary arteries. In this case the left ventricle was more affected than the right. The third case was exceptionally interesting owing to the limitation of fatty degeneration to the right ventricle as well as from the absence of physical signs of cardiac failure, except those associated with a relative emptiness of the heart and great vessels, and the weakness of the cardiac sounds, especially those heard over the right ventricle.

10. **Sclavo's Serum in Anthrax.**—The chief points of interest about Fergusson's case are: 1. The apparently long incubation period, ten days, if counted from the date that the patient got the blood of an anthrax-infected animal over his hand. 2. The rapid amelioration of the symptoms after the injection of the serum. Recovery without excision of the pustule. In most cases of recovery after treatment by Sclavo's serum the patients have been treated by excision as well.

11. **Antimony in Trypanosomiasis.**—The preparation used by Camac was metallic antimony in an oily medium. Ten minims, representing ½ grain, of the precipitated metallic antimony were injected into the muscles of the left buttock. Within an hour the patient experienced great local discomfort, which increased till the whole buttock was greatly swollen, painful and tender to such a degree that the least pressure of his body on the bed, where he was compelled to remain, caused him to call out with pain. Even with such cause removed the pain was so intense that morphin had to be used frequently. This condition, accompanied with sleeplessness, lasted for ten days, when the swelling, pain and tenderness gradually subsided, and within fourteen days from the date of injection the patient was able to walk about, and two days later all inconvenience had disappeared. When the area of swelling had lost the tenderness sufficiently to allow of palpation, it was found to be tense, hard, and fairly sharply defined to a circular area of about 18 to 20 cm. in diameter. There was no necrosis. For intravenous injection, the preparation used was antimony sodio tartrate. One-sixth of a grain in normal saline was injected into a vein of the arm. From Nov. 10, 1909, to Feb. 1, 1910, thirteen injections were given with intervals of about four days; on one occasion there was an interval of sixteen days, on another there was an interval of eight days. The thirteenth injection was received at about 11 a. m., Feb. 1, 1910.

About twenty minutes after leaving the laboratory, while on his way home the patient was suddenly seized with nausea and great weakness. He managed to reach his home unaided. Before Camac could reach him he had had a chill and violent abdominal pain. When Camac saw him he was greatly prostrated, complained of intense headache, and had a temperature of 103.6 F. This lasted five or six hours, when it subsided to normal. The blood was negative for trypanosomes. The urine showed great excess of indican, otherwise it was normal. For twelve days the weakness and abdominal distress continued, and on the thirteenth day from the former paroxysm he had, for six hours, a similar but somewhat less severe attack. Trypanosomes were not found at the time of this second fever, and have been absent on all subsequent examinations. Blood and spinal fluid inoculations into monkeys, rats and mice have been attended by negative results. From Oct. 9, 1909, to Jan. 31, 1910, the patient took daily by the mouth 1½ to 2 grains of antimony lithium tartrate, in 3 pints of water, in addition to the intravenous injections.

14. **Phenol Injections in Pulmonary Tuberculosis.**—Vallow injects 0.1 to 0.2 c.c. of a 1 per cent. solution of pure phenol in sterilized water once each week between the shoulders. He believes that early cases treated by this method give the best results.

15. **Carbon-Dioxid Snow in Trachoma.**—In forty of the fifty cases Harston effected a cure in from five to eighteen applications of carbon-dioxid snow. Three patients did not return and seven are still under treatment. At the first application the snow is applied to each part for fifteen seconds; later, when the patient is accustomed to the treatment, for as long as twenty, twenty-five and thirty seconds. The pain caused passes off at the end of two minutes, and is infinitesimal compared to the pain caused by bluestone, silver nitrate and such like caustics. The disease is considerably shortened in its course, and the resulting scarring is considerably less than when other caustics have been used.

16. **Administration of Diphtheria Antitoxin by Mouth.**—The points which Cumberlege believes to be in favor of oral administration of diphtheria antitoxin are as follows: Results are obtained within a few hours after being given, a far smaller dose is required (Cumberlege has never given more than 4,000 units at a time; a dose of 2,000 units, followed up, if necessary, by a further dose, is the usual amount given). By giving it in this way, it is possible to give continued dosage by making a mixture and ordering it to be given every two or four hours as the case may be. Another point in its favor is that no patient treated by him by mouth has shown signs of serum sickness, whereas either a rash or joint pains, or both, has nearly always occurred after the few injections given.

42. **Bradycardia in Nephritis.**—Danielopolu reports two cases of this kind. The first patient was a woman of 28 with acute nephritis coming on in the midst of good health; the pulse grew progressively slower, from 72 to 44, evidently the result of irritation of the regulating system of the heart, there being no auriculo-ventricular dissociation. The second patient had chronic nephritis and the bradycardia was likewise apparently of nervous origin in this case.

46 *Inflammatory Tuberculosis of the Glands with an Internal Secretion. (Tuberculose inflammatoire des glandes vasculaires sanguines.) A. Poncet and R. Leriche.

46. **Inflammatory Tuberculosis of the Glands with an Internal Secretion.**—Poncet comments on the striking fact that the viscera most often affected by inflammatory tuberculosis are most rarely the seat of the specific lesions of tuberculosis. This applies especially to the glands with an internal secretion; he describes conditions in each in turn, affirming that the conditions which are generally regarded as predisposing to tuberculosis are in reality the results of long established tuberculosis. The hypophysis, the adrenals, the ovaries, the thyroid—morbid changes in any of these from inflammation due to the tubercle bacilli may entail far-reaching consequences, but the prevailing conception to date has always put the cart before the horse, as it were, and he argues to prove that inflammation from tuberculosis in these glands is responsible for the insufficiency or excessive functioning which is manifested in so many different clinical syndromes. Insufficiency of the pancreas from a latent inflammatory tuberculous process, affecting the most vulnerable parts of the gland, that is, the islands of Langerhans, explains the shocking prevalence of tuberculosis among diabetics, recent statistics showing that fully 43 per cent. of all diabetics die of tuberculosis. It has been assumed that the lungs were rendered particularly non-resistant by the fact of the existing diabetes, but Poncet is convinced that the pulmonary phthisis is merely the terminal phase; the visceral tuberculosis is of long standing, and during years it has been insidiously at work engendering the disturbances and, by them, the nutritional disorder which others assume was merely preparing the soil for tuberculosis later. Obesity, infantilism, morbid sexual phenomena, etc., are all liable to be the manifestations of a loss of balance between the glands with an internal secretion or of direct injury of these glands from the effect of the unsuspected latent tuberculosis.

48 *Depression of the Skull in New-Born Infant Corrected by Corkscrew. (Cas d'enfoncement du crâne reduit par le tire-fond chez un nouveau-né.) E. Hauch.

48. **Obstetric Indentation of the Skull.**—In the case described there was an extensive depression of the frontal bone resulting from the application of forceps by a student. A little corkscrew, such as comes with certain makes of cologne, was sterilized and after the skin had been painted with tincture of iodin, the corkscrew was inserted into the bone with some little difficulty, but as soon as the tip had been introduced a single turn of the corkscrew was enough to give it a firm hold and the bone was thus readily drawn up into place. Hauch adds that shaving the skin and an incision are not necessary for the new-born. The dura separates readily from the bone and the procedure seems simple and harmless unless one of the rare blood-vessels in the dura should happen to be pierced, and this is easily avoided.

51. **Electric Burns of the Skull.**—Quénu discusses the subject in general, especially the management of such cases as advocated by different writers, and then reports a case from his own practice in which he removed the sequestrum without waiting for it to be thrown off spontaneously; he is convinced that this method offers superior advantages. He cut away at once the burned soft parts and found the bone below white, dry and free from vessels, but without signs of injury. Six months later the young man returned with suppuration around the edge of the wound, but no signs of irritation of the meninges. The patch of bone was then excised; the dura below was the seat of pronounced external pachymeningitis. A flap of scalp tissue was drawn over the gap left by excision of the bone, and reexamination a year later showed that there had been regeneration of bone over part of the defect, as could easily be felt by palpation through the hair. Quénu's only regret was that he had not excised the sequestrum earlier. The principles for treatment are the same as for scalping accidents. The eschar is aseptic, to start with.

57 *Exophthalmic Goiter in Men. A. Pic and S. Bonnamour.

53. **When the Tuberculous "Catch Cold."**—Sabourin classifies in a number of groups the "false colds" of the tuberculous, that is, symptoms from sudden congestion from any cause, and which the patients ascribe to casually catching cold. In one case, for instance, a young man with Hanot's cirrhosis of the liver had profuse purulent expectoration each time as the initial symptom of recurring exacerbation of the liver trouble, while at other times a mild apical tuberculous process gave scarcely any signs of its presence. When the tuberculous actually have caught cold, the flora of the upper air passages appear in the sputum to such an extent that this is an unfavorable time for examining for tubercle bacilli. The effect of the "cold" on the tuberculous process varies, Sabourin declares, according to the care the patient takes of himself. An ordinary "cold" is an infectious catarrh following chilling of the skin, and the tuberculous who take care to harden their skin seldom take "cold," and when they do, they take rational care of themselves while it lasts. In these conditions the "cold" is generally mild and leaves no relics after it has passed off, not aggravating the pre-existing lesions. But, a neglected cold in the tuberculous who are not taking good hygienic care of themselves is liable to stimulate the tubercle bacilli to renewed activity, or complications are set up by the infectious catarrh.

54. **Classification of Cases of Tuberculosis.**—Burnand discusses Bard's classification of tuberculosis, comparing it with his extensive clinical experience. Bard recognizes four forms: the parenchymatous, interstitial, bronchial and post-pleuritic, each with from two to four or more subdivisions. The parenchymatous form may be abortive or progressive, the latter including the caseous and fibrous and transition forms. Burnand expatiates in particular on the differentiation of an incipient progressive tuberculosis from the abortive form. The signs of abortive tuberculosis are exclusively local and mani-

28 [illegible] Gambiense in Glossina Pal- [illegible]

27. **Etiology of Blackwater Fever.**—The interesting points in the four cases cited by Pirie were: (1) The finding in each case of subtertian rings in the peripheral blood of the patients, before the onset of the hemoglobinuria. (2) In each case quinin was taken or given in order to treat the malaria, also before the hemoglobinuria when a small dose of quinin (2¼ gr.) was given. (3) The typical malarial temperature chart of Case 4 during the continuance of the hemoglobinuria. There were no malarial parasites at this time in this patient's peripheral blood, but it looks almost certain that sporulation was taking place in some of the internal organs. In all these cases no malarial parasites, though carefully looked for, were found after the onset of the hemoglobinuria. Each of these patients had the appearance of having been well saturated with malarial poisoning. The first and third case had not taken quinin, or had taken it very irregularly. Number two had not used his mosquito net and had most probably (though he said the contrary) taken his quinin irregularly. Case 4 had taken 5 grains of quinin daily. *All of these patients developed blackwater fever more or less* severely. It appears to Pirie to be more than a mere coincidence, that in each of these cases the onset of the hemoglobinuria should have followed the attempt to treat an attack of malarial subtertian fever with quinin. He thinks that only those persons whose resistance to the hemolytic action of the malaria parasite has been reduced by the continuous sporulation of the parasite in their systems are susceptible, and that in those persons a dose of quinin may be the actual exciting cause. This condition of susceptibility is *induced by neglect of, or irregularity in, the taking of the* daily dose of 5 grains of quinin. In cases in which one has been assured that 5 grains of quinin have been taken regularly every day, Pirie suggests that it may be that certain types of constitution are so peculiarly susceptible to malarial infection that the 5 grains of quinin daily is not sufficient to prevent the continuous sporulation of the parasite in the system, though that dose may be sufficient to make the patient take to bed. These persons get anemic and debilitated, and gradually develop that unstable condition of the red blood-corpuscles that may ultimately end in an attack of blackwater fever.

34 *New Method of Performing Colporrhaphy. W. B. Bell.

34. **Colporrhapy.**—In Bell's method, after an oval-shaped area (about 1½ or more inches broad in the widest part) of vaginal wall has been removed, the underlying bladder is entirely separated from the remaining anterior vaginal wall. All bleeding points are then carefully tied. Mattress sutures of 40-day chromic catgut are everted. The sutures, when tied, cause large, raw under-surfaces of vaginal wall to be brought into contact, and form a ridge running the whole length of the anterior vaginal wall. Bell cautions that the mattress sutures should not be tied too tightly, nor should the anterior vaginal wall be stretched too much when the operation is completed. If it be found after suturing that the everted edges project more than ½ inch they may be trimmed down. Finally, a running overhand stitch of fine catgut may be used to unite the free margins and to prevent the exposure of a raw edge. The appearance, some months after operation, of the ridge, which widens slightly, resembles that of a normal anterior column.

41 Influence of Phenol on the Virus of Rabies. W. Sawtschenco.

37. **Experimental Research on Cholera.**—Choukevitch reports experiments on rabbits which failed to show that vaccination had any protecting influence against cholera by the intestinal route. His research further gave negative results in regard to the nitrites as an essential factor in development of *cholera, and also in regard to the anticholera cocci of Nitsch.*

38. **Prophylaxis of Cholera.**—Metchnikoff thinks that the present methods of vaccination against cholera are bound to fail as intoxication from the cholera toxins in the intestines cannot be neutralized by the methods effectual in infections. He reviews the total field of anticholera vaccination to date, saying that the statistics of the vaccination against cholera on a large scale at St. Petersburg and in India are misleading, as the vaccinators were careful to vaccinate only those least liable to contract the disease, skipping the young, the elderly and those with chronic disease and, according to directions, vaccinating only the healthy "so as not to discredit the method," and the records are defective of the vaccinated who contracted cholera. He insists that the results of experiments on animals should be given greater credit in applying the conclusions to man, and that the constant failure of Choukevitch's experimental anticholera vaccination and of Metchnikoff's attempts to immunize chimpanzees against typhoid fever should be given due weight. He relates that he has recently had a personal experience which has convinced him anew that hygienic measures are reliable as the safest and most certain means of warding off typhoid and cholera. His manservant, who prepared his breakfast and resided in the house and was the husband of the maid-servant, contracted typhoid fever. As Metchnikoff had never had typhoid he considered the question of being vaccinated but concluded to rely on hygienic measures alone. No food was served except articles that had been cooked, and an alcohol lamp or gas stove and a dish of boiling water ensured the sterility of the cup and plate and of the knife, fork and spoon. By these simple means the people in the house were protected against typhoid, no further case developing, and he is convinced that similar measures will prove equally effectual against all intestinal diseases. At St. Petersburg, he adds, boiling the drinking water protected people against cholera. Vaccination against intestinal disease should be reserved for exceptional conditions, as for forced marches in time of war. When vaccination is done it should be with scientific care to record the observations and make them resemble as much as possible exact scientific experiments. This chapter of human vaccinations, he says, is far from its definite conclusion, and experience is proving more and more the efficacy of careful and intelligent hygienic prophylaxis.

Vincent presents arguments against Metchnikoff's conclusions in regard to antityphoid vaccination, declaring that chimpanzees are so frail in a northern climate that their nonresistance may be ascribed to other causes, it being so difficult to keep monkeys alive in captivity at Paris. The results of the recent antityphoid vaccinations in America, he adds, are proving the efficacy of this method of prophylaxis which even Metchnikoff admits has a sound theoretic basis.

53. **When the Tuberculous "Catch Cold."**—Sabourin classifies in a number of groups the "false colds" of the tuberculous, that is, symptoms from sudden congestion from any cause, and which the patients ascribe to casually catching cold. In one case, for instance, a young man with Hanot's cirrhosis of the liver had profuse purulent expectoration each time as the initial symptom of recurring exacerbation of the liver trouble, while at other times a mild apical tuberculous process gave scarcely any signs of its presence. When the tuberculous actually have caught cold, the flora of the upper air passages appear in the sputum to such an extent that this is an unfavorable time for examining for tubercle bacilli. The effect of the "cold" on the tuberculous process varies, Sabourin declares, according to the care the patient takes of himself. An ordinary "cold" is an infectious catarrh following chilling of the skin, and the tuberculous who take care to harden their skin seldom take "cold," and when they do, they take rational care of themselves while it lasts. In these conditions the "cold" is generally mild and leaves no relics after it has passed off, not aggravating the pre-existing lesions. But, a neglected cold in the tuberculous who are not taking good hygienic care of themselves is liable to stimulate the tubercle bacilli to renewed activity, or complications are set up by the infectious catarrh.

54. **Classification of Cases of Tuberculosis.**—Burnand discusses Bard's classification of tuberculosis, comparing it with his extensive clinical experience. Bard recognizes four forms: the parenchymatous, interstitial, bronchial and post-pleuritic, each with from two to four or more subdivisions. The parenchymatous form may be abortive or progressive, the latter including the caseous and fibrous and transition forms. Burnand expatiates in particular on the differentiation of an incipient progressive tuberculosis from the abortive form. The signs of abortive tuberculosis are exclusively local and mani-

27 *Etiology of Blackwater Fever. G. J. Pirie.
28 Development of Trypanosoma Gambiense in Glossina Palpalis. Sir D. Bruce.

27. **Etiology of Blackwater Fever.**—The interesting points in the four cases cited by Pirie were: (1) The finding in each case of subtertian rings in the peripheral blood of the patients, before the onset of the hemoglobinuria. (2) In each case quinin was taken or given in order to treat the malaria, also before the hemoglobinuria when a small dose of quinin (2¼ gr.) was given. (3) The typical malarial temperature chart of Case 4 during the continuance of the hemoglobinuria. There were no malarial parasites at this time in this patient's peripheral blood, but it looks almost certain that sporulation was taking place in some of the internal organs. In all these cases no malarial parasites, though carefully looked for, were found after the onset of the hemoglobinuria. Each of these patients had the appearance of having been well saturated with malarial poisoning. The first and third case had not taken quinin, or had taken it very irregularly. Number two had not used his mosquito net and had most probably (though he said the contrary) taken his quinin irregularly. Case 4 had taken 5 grains of quinin daily. All of these patients developed blackwater fever more or less severely. It appears to Pirie to be more than a mere coincidence, that in each of these cases the onset of the hemoglobinuria should have followed the attempt to treat an attack of malarial subtertian fever with quinin. He thinks that only those persons whose resistance to the hemolytic action of the malaria parasite has been reduced by the continuous sporulation of the parasite in their systems are susceptible, and that in those persons a dose of quinin may be the actual exciting cause. This condition of susceptibility is induced by neglect of, or irregularity in, the taking of the daily dose of 5 grains of quinin. In cases in which one has been assured that 5 grains of quinin have been taken regularly every day, Pirie suggests that it may be that certain types of constitution are so peculiarly susceptible to malarial infection that the 5 grains of quinin daily is not sufficient to prevent the continuous sporulation of the parasite in the system, though that dose may be sufficient to make the patient take to bed. These persons get anemic and debilitated, and gradually develop that unstable condition of the red blood-corpuscles that may ultimately end in an attack of blackwater fever.

34 *New Method of Performing Colporrhaphy. W. B. Bell.

34. **Colporrhapy.**—In Bell's method, after an oval-shaped area (about 1½ or more inches broad in the widest part) of vaginal wall has been removed, the underlying bladder is entirely separated from the remaining anterior vaginal wall. All bleeding points are then carefully tied. Mattress sutures of 40-day chromic catgut are everted. The sutures, when tied, cause large, raw under-surfaces of vaginal wall to be brought into contact, and form a ridge running the whole length of the anterior vaginal wall. Bell cautions that the mattress sutures should not be tied too tightly, nor should the anterior vaginal wall be stretched too much when the operation is completed. If it be found after suturing that the everted edges project more than ½ inch they may be trimmed down. Finally, a running overhand stitch of fine catgut may be used to unite the free margins and to prevent the exposure of a raw edge. The appearance, some months after operation, of the ridge, which widens slightly, resembles that of a normal anterior column.

41 Influence of Phenol on the Virus of Rabies. W. Sawtschenco.

37. **Experimental Research on Cholera.**—Choukevitch reports experiments on rabbits which failed to show that vaccination had any protecting influence against cholera by the intestinal route. His research further gave negative results in regard to the nitrites as an essential factor in development of cholera, and also in regard to the anticholera cocci of Nitsch.

38. **Prophylaxis of Cholera.**—Metchnikoff thinks that the present methods of vaccination against cholera are bound to fail as intoxication from the cholera toxins in the intestines cannot be neutralized by the methods effectual in infections. He reviews the total field of anticholera vaccination to date, saying that the statistics of the vaccination against cholera on a large scale at St. Petersburg and in India are misleading, as the vaccinators were careful to vaccinate only those least liable to contract the disease, skipping the young, the elderly and those with chronic disease and, according to directions, vaccinating only the healthy "so as not to discredit the method," and the records are defective of the vaccinated who contracted cholera. He insists that the results of experiments on animals should be given greater credit in applying the conclusions to man, and that the constant failure of Choukevitch's experimental anticholera vaccination and of Metchnikoff's attempts to immunize chimpanzees against typhoid fever *should* be given due weight. He relates that he has recently had a personal experience which has convinced him anew that hygienic measures are reliable as the safest and most certain means of warding off typhoid and cholera. His manservant, who prepared his breakfast and resided in the house and was the husband of the maid-servant, contracted typhoid fever. As Metchnikoff had never had typhoid he considered the question of being vaccinated but concluded to rely on hygienic measures alone. No food was served except articles that had been cooked, and an alcohol lamp or gas stove and a dish of boiling water ensured the sterility of the cup and plate and of the knife, fork and spoon. By these simple means the people in the house were protected against typhoid, no further case developing, and he is convinced that similar measures will prove equally effectual against all intestinal diseases. At St. Petersburg, he adds, boiling the drinking water protected people against cholera. Vaccination against intestinal disease should be reserved for exceptional conditions, as for forced marches in time of war. When vaccination is done it should be with scientific care to record the observations and make them resemble as much as possible exact scientific experiments. This chapter of human vaccinations, he says, is far from its definite conclusion, and experience is proving more and more the efficacy of careful and intelligent hygienic prophylaxis.

Vincent presents arguments against Metchnikoff's conclusions in regard to antityphoid vaccination, declaring that chimpanzees are so frail in a northern climate that their nonresistance may be ascribed to other causes, it being so difficult to keep monkeys alive in captivity at Paris. The results of the recent antityphoid vaccinations in America, he adds, are proving the efficacy of this method of prophylaxis which even Metchnikoff admits has a sound theoretic basis.

42. **Bradycardia in Nephritis.**—Danielopolu reports two cases of this kind. The first patient was a woman of 28 with acute nephritis coming on in the midst of good health; the pulse grew progressively slower, from 72 to 44, evidently the result of irritation of the regulating system of the heart, there being no auriculo-ventricular dissociation. The second patient had chronic nephritis and the bradycardia was likewise apparently of nervous origin in this case.

46 *Inflammatory Tuberculosis of the Glands with an Internal Secretion. (Tuberculose inflammatoire des glandes vasculaires sanguines.) A. Poncet and R. Leriche.

46. **Inflammatory Tuberculosis of the Glands with an Internal Secretion.**—Poncet comments on the striking fact that the viscera most often affected by inflammatory tuberculosis are most rarely the seat of the specific lesions of tuberculosis. This applies especially to the glands with an internal secretion; he describes conditions in each in turn, affirming that the conditions which are generally regarded as predisposing to tuberculosis are in reality the results of long established tuberculosis. The hypophysis, the adrenals, the ovaries, the thyroid—morbid changes in any of these from inflammation due to the tubercle bacilli may entail far-reaching consequences, but the prevailing conception to date has always put the cart before the horse, as it were, and he argues to prove that inflammation from tuberculosis in these glands is responsible for the insufficiency or excessive functioning which is manifested in so many different clinical syndromes. Insufficiency of the pancreas from a latent inflammatory tuberculous process, affecting the most vulnerable parts of the gland, that is, the islands of Langerhans, explains the shocking prevalence of tuberculosis among diabetics, recent statistics showing that fully 43 per cent. of all diabetics die of tuberculosis. It has been assumed that the lungs were rendered particularly non-resistant by the fact of the existing diabetes, but Poncet is convinced that the pulmonary phthisis is merely the terminal phase; the visceral tuberculosis is of long standing, and during years it has been insidiously at work engendering the disturbances and, by them, the nutritional disorder which others assume was merely preparing the soil for tuberculosis later. Obesity, infantilism, morbid sexual phenomena, etc., are all liable to be the manifestations of a loss of balance between the glands with an internal secretion or of direct injury of these glands from the effect of the unsuspected latent tuberculosis.

48 *Depression of the Skull in New-Born Infant Corrected by Corkscrew. (Cas d'enfoncement du crâne reduit par le tire-fond chez un nouveau-né.) E. Hauch.

48. **Obstetric Indentation of the Skull.**—In the case described there was an extensive depression of the frontal bone resulting from the application of forceps by a student. A little corkscrew, such as comes with certain makes of cologne, was sterilized and after the skin had been painted with tincture of iodin, the corkscrew was inserted into the bone with some little difficulty, but as soon as the tip had been introduced a single turn of the corkscrew was enough to give it a firm hold and the bone was thus readily drawn up into place. Hauch adds that shaving the skin and an incision are not necessary for the new-born. The dura separates readily from the bone and the procedure seems simple and harmless unless one of the rare blood-vessels in the dura should happen to be pierced, and this is easily avoided.

52 Pathogenesis of Painful Valgus Flat-Foot. (Sur la pathogénie du pied plat valgus douloureux.) R. Leriche.

51. **Electric Burns of the Skull.**—Quénu discusses the subject in general, especially the management of such cases as advocated by different writers, and then reports a case from his own practice in which he removed the sequestrum without waiting for it to be thrown off spontaneously; he is convinced that this method offers superior advantages. He cut away at once the burned soft parts and found the bone below white, dry and free from vessels, but without signs of injury. Six months later the young man returned with suppuration around the edge of the wound, but no signs of irritation of the meninges. The patch of bone was then excised; the dura below was the seat of pronounced external pachymeningitis. A flap of scalp tissue was drawn over the gap left by excision of the bone, and reexamination a year later showed that there had been regeneration of bone over part of the defect, as could easily be felt by palpation through the hair. Quénu's only regret was that he had not excised the sequestrum earlier. The principles for treatment are the same as for scalping accidents. The eschar is aseptic, to start with.

56 Intonation and Memory. (Note relative à la chanson du langage.) J. Lépine.
57 *Exophthalmic Goiter in Men. A. Pic and S. Bonnamour.

53. **When the Tuberculous "Catch Cold."**—Sabourin classifies in a number of groups the "false colds" of the tuberculous, that is, symptoms from sudden congestion from any cause, and which the patients ascribe to casually catching cold. In one case, for instance, a young man with Hanot's cirrhosis of the liver had profuse purulent expectoration each time as the initial symptom of recurring exacerbation of the liver trouble, while at other times a mild apical tuberculous process gave scarcely any signs of its presence. When the tuberculous actually have caught cold, the flora of the upper air passages appear in the sputum to such an extent that this is an unfavorable time for examining for tubercle bacilli. The effect of the "cold" on the tuberculous process varies, Sabourin declares, according to the care the patient takes of himself. An ordinary "cold" is an infectious catarrh following chilling of the skin, and the tuberculous who take care to harden their skin seldom take "cold," and when they do, they take rational care of themselves while it lasts. In these conditions the "cold" is generally mild and leaves no relics after it has passed off, not aggravating the pre-existing lesions. But, a neglected cold in the tuberculous who are not taking good hygienic care of themselves is liable to stimulate the tubercle bacilli to renewed activity, or complications are set up by the infectious catarrh.

54. **Classification of Cases of Tuberculosis.**—Burnand discusses Bard's classification of tuberculosis, comparing it with his extensive clinical experience. Bard recognizes four forms: the parenchymatous, interstitial, bronchial and post-pleuritic, each with from two to four or more subdivisions. The parenchymatous form may be abortive or progressive, the latter including the caseous and fibrous and transition forms. Burnand expatiates in particular on the differentiation of an incipient progressive tuberculosis from the abortive form. The signs of abortive tuberculosis are exclusively local and mani-

festly mild. The lesion has already passed its prime and is declining when discovered, but at the same time it is better to tend a few cases of "still-born tuberculosis" rather than to let one incipient progressive case escape treatment. A young man had a slight hemoptysis in the midst of apparent health; there was no expectoration, fever, cough or loss of weight and none developed later, but a very slight tendency to dulness over the right apex was discovered and expiration was a trifle prolonged. There was also a history of congestion at the right apex in childhood and a pleurisy. The diagnosis of abortive tuberculosis was confirmed by the persisting good health to date. In a second case, similar in other respects, there was a loss of nearly 4½ pounds, an old catarrhal hawking each morning became a dry cough with a slight hemoptysis a month later, accompanied by a very slight rise in temperature. This case is classed as incipient progressive tuberculosis, as also a third typical case in which the patient had lost slightly in weight, with a briefly transient subfebrile temperature at one time. Although the local signs were insignificant, these slight general symptoms gave the alarm, confirmed by the rapidly progressive course of the disease. Burnand's article is not completed in this number.

55. **Spleen Organotherapy in Tuberculosis.**—Bayle has obtained such good results in this line that he does not hesitate to regard spleen tissue or extract as a specific method of treatment for tuberculosis. He gives 100 gm. of raw pork spleen tissue daily for three weeks and recommences again ach time after an interval of two weeks. It is readily taken n soup or preserves, he says, or extracts of the spleen may e used. He commenced this treatment about 1903, and now as a record of 150 patients with pulmonary tuberculosis nd twenty-two with bone or joint tuberculosis, all given a ystematic course of spleen organotherapy, with a complete ure in 75 per cent. of the patients, only four not showing narked benefit under it. Joly has also cured 93 per cent. of is ninety patients. All the local processes heal under this treatment ten times faster, Bayle says, than is the case under any other methods of treatment. It is readily applied and causes no febrile reaction and no by-effects. He explains its ific action by assuming some hitherto unknown function e spleen—possibly a colloid-producing function.

. **Exophthalmic Goiter in Men.**—Pic and Bonnamour rt two cases in male adults. In 563 cases of exophthalgoiter which they found on record, 109 of the patients men, less than 20 per cent., but all authors seem to gree that the affection generally has a stormier onset and runs a more serious course in men than in women, so that active measures should be instituted from the start, including prompt surgical aid if the medical prove inadequate.

58. **Krönlein's Operation for Retrobulbar Tumor.**—Bircher adds another successful case to the 117 cases on record (up to 1905) in which this operation has been done. He urges its wider adoption, as it is comparatively simple and easy and not disfiguring.

61. **Modified Aseptic Suture of the Intestines.**—Rostowzew has slightly modified his clamp which permits suture of the clamped tissues, and shows the method of its use in thirteen illustrations.

63. **Exposure of the Middle Cranial Fossa.**—Ruttin gives an illustrated description of his simple method of access to an extensive extradural abscess originating in the middle ear. He also reports five cases in which this technic was applied with a successful outcome in three. The other patients succumbed to other complications. Even pus in the cerebrospinal fluid on lumbar puncture does not contra-indicate the operation, he declares.

68. **Postoperative Gastro-Intestinal Hemorrhages.**—Winiwarter's experience has demonstrated that hemorrhage is liable to occur in the gastro-intestinal tract from retrograde embolism or paralysis of the vessels from toxins in the blood after major operations anywhere on the body. These hemorrhages generally occur during the first three days after the operation. The changes in the stomach responsible for them rapidly heal and should not be regarded as an ulcer or precursor of an ulcer. The prognosis is grave when the hemorrhages are associated with severe general infection, as he shows by thirty cases from his experience. In treatment he recommends washing out the stomach with a silver nitrate solution. The article issues from von Eiselsberg's clinic at Vienna, this surgeon having been the first to call attention to the frequency of gastro-intestinal hemorrhage after laparotomies. Busse compiled ninety-six cases from the literature up to 1905; the thirty cases Winiwarter reviews all occurred in the clinic in the last five years. The necropsy findings confirmed the frequent causal importance of local injury in the stomach or duodenum from obstruction of veins by retrograde embolism from detached thrombi from ligated veins in the omentum or mesentery or thrombosis spreading directly from them. In rare cases injury of the central nervous system was responsible, but more frequent was a toxic paralysis of the vessels. The anesthetic, the vomiting and a general predisposition were also evident factors.

Berliner klinische Wochenschrift

79 Infant Welfare from Standpoint of Campaign Against Tuberculosis. J. Landsberger.

73. **Oatmeal in Diabetes.**—Magnus-Levy's experience has demonstrated, he asserts, that the advantages of oatmeal in the diet of diabetics are mostly on the negative side; that is, by the absence of *meat.* At the same time he admits that the oatmeal starch has certain special features different from those of the other cereals, particularly evident in its behavior in the intestines. He reiterates von Noorden's caution that a course of oatmeal should always be preceded by a few days of dieting, less than 50 gm. of bread being allowed in this preliminary period. Another point is that the oatmeal diet must not be kept up for weeks at a time. Three or four days are enough, then a vegetable day, and then, after a pause of a few days, the oatmeal is resumed again as before. The details of one such case are tabulated, showing how after five oatmeal courses (250 gm. oatmeal porridge) the patient acquired tolerance under these measures and was able to eat 50 gm. of bread without glycosuria, while before this on a strict diet, he eliminated from 50 to 70 gm. of sugar and large amounts of acetone. The oatmeal is not required for cases other than the severest and moderately severe. The method to be done properly and well requires daily deter-

mination of the proportion of sugar in the urine. Certain diabetics may do equally well with rye or wheat meal instead of oatmeal. He adds that no satisfactory theory to explain the beneficial action of the cereals in diabetes has yet been presented beyond those suggested here.

74. **Idiopathic Enlargement of the Spleen.**—This is practically the last communication from the late Professor Senator. The case described resembled Banti's disease in some respects, but the absence of ascites and of the typical blood changes seemed to exclude this disease. The patient was a man of 40, and very little benefit followed splenectomy, but the persisting disturbances seem to be more in the nature of neurasthenia. Nothing organic can be found to explain them, and it is possible that his business, publishing books, may be too strenuous for him.

75. **Blood Findings in Roentgenologists.**—A Vienna specialist in *x*-ray work and another at Munich both succumbed not long ago to lymphatic leukemia, and Schwarz found the changes in the blood characteristic of this disease in a chemist long engaged in the production of radium. He also cites a fatal case in an American roentologist. This prevalence of lymphatic leukemia among roentologists was confirmed by examination of ten other, apparently healthy, roentologists. In all, the blood findings indicated some injury of the "granulocyte" system in the bone marrow or circulating blood. This is paralleled by an increase in the lymphoid elements—possibly a compensating process, but more likely the result of irritation from the action of the *x*-rays. These changes in the blood were more severe the more extensive and prolonged the work with the *x*-rays.

86 Prophylaxis of Tuberculosis. O. Moszelk.

82. **Enuresis as a Manifestation of Myelodysplasia.**—Fuchs explains enuresis in certain cases as the result of an occult spina bifida, which in turn is due to defective development of the spinal cord, a myelodysplasia as he calls it. Peritz has examined twenty guardsmen with enuresis and two other adults and twenty children, and the Roentgen findings all confirm this assumption of defective development of the spinal cord and spine as an important factor in the enuresis. He found the myelodysplasia pronounced in 68.2 per cent. of the adults and in 35 per cent. of the children. Syndactylia was also frequent among these individuals and disturbances in the thermic sense. Instead of the normal small triangle of the sacral hiatus the opening is wide and extends high up with or without bone crossbars. The dehiscence shows up well in the radiograph. Defective development of the lower part of the spinal cord explains the success of Cathelin's epidural injections in treatment in certain cases of enuresis. The fluid distends the cicatricial tissue and crossbars and releases the nerves from the pressure of the abnormal bands, etc., and they resume normal functioning. The individual then regains volitional control of the bladder sphincter. The effect is purely mechanical, but it is almost certain to cure the enuresis in the cases of this category. The aim in treatment of enuresis should be to discover the actual cause of the condition; and if myelodysplasia is suspected, to remedy conditions in this or some similar way.

83. **Causal Treatment of Diabetes.**—Funck set himself to the task of discovering some cooperating factor besides the anomaly in the utilization of sugar as responsible for the causation of diabetes, and he states that gastro-intestinal disturbances were found unexpectedly prominent when the cases were studied from this dual causal standpoint. Instead of devoting all the energies to curing the disturbance in the metabolism of carbohydrates, he has obtained surpassing results by attacking the cause which he suspected of being responsible for the disturbance in the metabolism, as he explains in detail. He insists that the disturbance may be in the fixation as well as in the oxidation of the carbohydrates, and that unsuspected chronic gastritis or gastrogenous enteritis may be the primal factor of the disturbance, or at least responsible for exacerbations. In the severest case reported, the patient in incipient coma, he introduced a fine sound into the duodenum and flushed the intestines, sending through in thirty-eight hours 9 liters of a physiologic salt solution, at the rate of a drop a second, utilizing in this way the enormous area of mucous membrane surface in the intestine. No food was allowed but milk for four days, and after that mostly rice and milk, with hydrochloric acid as the only drug. The patient was soon free from sugar and attends to a very responsible business. Milk and rice are the main reliance in diet in this and the other cases cited.

87. **Diabetes.**—Minkowski discusses the latest conceptions in regard to the cause of the overloading of the organism with sugar, and in which organs is located the anomaly responsible for the disturbances. The reaction to the hitherto prevailing over-strict deprivation of carbohydrates is swinging to the other extreme, he fears, but he does not hesitate to admit that he has derived unmistakable benefit from a course of oatmeal diet in certain cases. In several recent experiences, patients with impending or already installed coma seemed to have been dragged from the jaws of death by the oatmeal cure. But, he continues, it is adapted only for a small group of diabetics, and the benefit derived is not permanent. He thinks the benefit from the oatmeal lies partly in the restriction of protein; the fat also should be reduced as much as possible in combating the acidosis. Restriction of protein not only does away with this source of sugar production, but it also reduces the metabolism as a whole. Naunyn, he adds, has especially emphasized the advantages of reducing the amount of the total metabolic processes as a distinct gain in many cases of diabetes. It is therefore wise to reduce the amount of muscular exercise in severe cases of diabetes. In the mild forms there is less danger of doing harm with a very strict course of dieting, while the aim is not merely to tide the patient along, but to cure or at least to increase the tolerance for sugar permanently.

88. **Tuberculosis of the Female Genitalia.**—Franqué is convinced that the frequent primary invasion of the Fallopian tubes in genital tuberculosis can be explained only by infection from the vagina in the majority of cases. It has been his experience that nodules could be palpated in the pouch of Douglas with other than tuberculous affections, and he cites some cases in which adenomatous proliferations spread from the uterus to the floor of the pelvis and to the rectum. The tuberculin reaction he also found frequently misleading with tuberculosis of the female genitalia, being negative and especially without any focal reaction in some cases which proved to be typical tuberculosis, while in others there was a positive reaction when the course of the cases and operations failed to reveal the least tuberculous lesions in the genitalia. In one case in this latter group the trouble proved to be a hematoma in each ovary in a virgin; in another there were multiple myomas in the uterus with inflammation around the uterus and a hematoma in one ovary. He inquires whether others have obtained positive tuberculin reactions with old encapsulated hematomas and hematoceles. In another case

THE FUNDAMENTAL PRINCIPLES OF PEDIATRICS [*]

HENRY DWIGHT CHAPIN, M.D.
NEW YORK

Pediatrics, at present, may be divided into two parts; first, that relating to the treatment of disease and perversion of function; second, that concerned with the production of well-developed physique in children. More attention is usually paid to the first than to the second of these branches.

If its scope were broadened, pediatrics might be defined as that branch of science which concerns itself with the animal aspect of the production of human beings. This science could then be divided into two parts; first, that devoted to the production of the highest development of the human being as an animal; second, that concerned with the management of the growing human animal when malformed, or with perverted functions, or subjected to mechanical injury, or attacked by parasitic microorganisms, or poisoned. It is evident then, that the pediatrist should be versed in general biology, bacteriology, protozoology, chemistry and physics.

While the public is not yet fully educated to the advantages of consulting a pediatrist before children are sick, it would be to the advantage of children, of parents, and of the community at large if every child during its most active period of growth were supervised by a well-equipped pediatrist, meaning by this, one who has had a broad training in general science as well as in a special department of medicine. If a physician undertakes to look after the development of a child, he should thoroughly understand the broad principles of human development and of animal life in general; it is not enough simply to be able to follow the ideas of some prominent teacher or authority.

It would prove an advantage to all physicians if the fundamental principles of the management of infants could be firmly established and thus taken out of the field of discussion. In order to attain this result, it is essential that the teachings concerning the chemistry of feeding be in accord with the general science of chemistry, that the problems of infancy falling in the province of physics be recognized as such, and that the teachings concerning animal life and development be true to those principles which have been found to apply to life in all its forms.

While medical men stand well in the forefront when it comes to the relations of human beings and animals to bacteria and protozoa, it must be confessed that they often lag behind in respect to the general care, nutrition and development of the human being in relation to his environment. The physician may broaden out to advantage at the points where science at large touches these problems.

The life-cycle of human beings, like that of all forms of animal life, may be sharply divided into two periods: first, that in which all of the food is derived from the mother's body in specialized forms; second, that in which none of the food is obtained from the mother's body but a wide variety of forms is taken. It is during the period in which the mother secretes the specialized forms of food that the tissues are produced and become differentiated into organs. When the organs of nutrition are developed, such forms of food are no longer needed and the infant has become a living machine that is able from food to build the future adult. This living machine is operated on much the same principle as a mechanical engine. It takes in fats, sugars and starches, and, by combining them with air procured through the lungs, obtains a supply of energy. This energy, when expended, appears in the form of heat which must be removed as fast as it is liberated, and it is accordingly found that all animals are provided with two cooling systems. For ordinary conditions, radiation of heat into the surrounding air is sufficient, but when the temperature of the air is nearly as high as that of the body, or higher, radiation fails to cool sufficiently, and heat is removed by being changed into latent heat through the evaporation of perspiration.

An infant taking 36 ounces of breast milk daily receives food yielding about 792 calories, or enough heat to raise the temperature of a 14-pound baby 113 C. In other words, this food will liberate enough heat to raise the temperature of the infant above the boiling-point of water. It may easily be appreciated, then, how important is the proper working of the infant's cooling system; yet how few realize that infants and all animals have cooling systems, and that the life habits of many animals are largely controlled by them! Some animals of enormous strength, such as the lion and cat tribe, are incapable of prolonged effort because they cannot get rid of the heat liberated as fast as it is produced.

A large part of the sickness among infants in hot weather may be due to ineffective cooling of the living animal motor. Imagine an infant on a hot day lying in a crib surrounded by curtains. Air movement is stopped, and the atmosphere around the infant becomes so saturated with water vapor from the evaporated perspiration that no more can evaporate, with the result that the infant's cooling system breaks down and vomiting and diarrhea may ensue. Boiling water, and vapor from it, have the same temperature, 212 F., yet the vapor has absorbed almost one thousand degrees of heat and rendered it latent or insensible. As long as the air is not there was effusion in the abdominal cavity and signs of tuberculosis in the lungs, suggesting tuberculous ascites, and the pregnancy was artificially interrupted on this account, as the tuberculin reaction had been positive, but the course of the case revealed a gall-stone trouble with no further signs of tuberculosis. Each time, however, the uterus reacted to the three tuberculin injections with hemorrhage. but no trace of tuberculosis could be found in the uterus adnexa after their removal nor in the scrapings of the uterus. In another case the test injection of tuberculin caused such serious peritonitic symptoms with ileus and collapse that the patient's life was in danger. This case warns of the necessity for care in applying the tuberculin test when there are reasons for assuming the existence of adhesions between the intestines. Schlimpert and Zöppritz have also recently called attention anew to the unreliability of the tuberculin test in affections of the female genital organs. Franqué operates on principle whenever convinced of the tuberculous nature of a tumor in the uterus adnexa, if it seems to be the only or the predominant manifestation of the disease. He thus operated in thirty-seven cases over five years ago, including nineteen with genital and eighteen with peritoneal tuberculosis, and all the patients made a smooth recovery and were much benefited with a single exception. This patient had the rectum injured during the operation, as it was closely adherent to the seriously diseased ovary, but the woman's fistula has since healed and she is now married. In three cases there was suppuration in the scar, fourteen and fifteen months later after apparently smooth primary healing, but the lesion soon healed. He regards a tuberculous process in the genital organs as a very serious lesion if left unmolested. In one case after an apparent cure under medical measures only, the process perforated into the rectum. When the uterine mucosa becomes involved the process may be regarded as "open," and the patient thus becomes a source of danger for others, to say nothing of the danger for herself of mixed infection from the intestines. He cites three new cases to show that genital tuberculosis displays scarcely any tendency to spontaneous cure; a concomitant tuberculous peritonitis healed completely. while the genital lesions persisted unmodified or gradually progressing.

---

[*] President's Address before the American Pediatric Society at Mohonk Lake, N. Y., May 31, 1911.

89. **Hemorrhage in the Spleen.**—In the first case the patient, a physician of 37, had verrucous endocarditis, but it revealed no signs of its presence until embolic obstruction occurred in the spleen, the infarct leading to hemorrhage and rupture. In the second case a young man, a hemophilic with pulmonary tuberculosis, succumbed with the same symptoms, indicating hemorrhage in the spleen, rupturing the organ.

92. **Improved Technic for Thiersch Flaps.**—Schepelmann extols the advantages of tincture of iodin for sterilization of the skin before taking the flaps. Only the upper layer of the epithelium was thrown off in consequence, even when the tincture had been applied three times. Another simplification of the technic which he advocates is the use of ethyl chlorid local anesthesia, and a special knife which automatically regulates the thickness of the slice. The freezing does not seem to impair the vitality of the flaps. The frozen flap keeps smooth and flat, so that there is no trouble from its crumpling as it is transplanted. Superheated air has been doing good service in the after-treatment of the transplanted flaps.

103. **The Vaginal Method in Gynecology.**—All the articles in this supplementary number of the *Monatsschrift* are from the institute for obstetrics and gynecology in charge of Prof. von Ott at St. Petersburg. He is an ardent champion of the vaginal route for operations within the pelvis, and his communication is accompanied by numerous illustrations showing his special technic for illumination of the interior of the pelvis through the vagina and also for direct inspection of the bladder and rectum. (Some of the illustrations are the same as those reproduced in The Journal, Aug. 23, 1902, p. 458.) His experience with the 1,137 cases summarized in these various articles and those of his assistants confirm, he thinks, the numerous advantages of the vaginal over the abdominal route wherever it is practicable. Soboleff reports his experiences with appendectomy by way of the vagina secondary to a gynecologic operation, having found the illumination through the colpotomy wound ample for the purpose.

104. **Carbohydrates in Diabetes.**—Blum gives a number of tables and further arguments to recapitulate and supplement those he has recently published elsewhere. (One of his articles was summarized in these columns August 5.) He is docent at Strasburg, and the work issues from the medical clinic in charge of Moritz, the scene of much pioneer research on the nutritional diseases. He reiterates anew that the aim in treatment is to put an end to the glycosuria, and that nothing is able to do this in such a simple, rapid and harmless way as restriction to oatmeal or wheat flour. But there can be no hard-and-fast rule for this; the amount of the carbohydrate allowed must vary with the severity of the disease.

105. **Determination of Epinephrin in the Blood.**—A number of physiologic experiments and tests are related by O'Connor to determine the presence of epinephrin in the blood. His research seems to indicate that blood serum contains not only epinephrin, but some other substances with similar properties. He found that the action of serum was greater on the rabbit uterus than the action of an epinephrin solution of the same concentration of epinephrin. This difference is suggested still more forcibly by the fact that the pure solution of epineprin has an inhibiting action on the intestine, while serum from the carotid, containing the same proportion of epinephrin, has a stimulating action on the bowel.

106. **Specificity of Antianaphylaxis.**—Calvary's experiments seem to indicate that an alien serum has the same action as a homologous serum in respect to production of anaphylaxis and protection against it, but that there is a great quantitative difference between them, sixty times as much of the former as of the latter being required to accomplish the same results. The conditions are similar to those with precipitation and agglutination; the response is a group response, and it occurs with special intensity exclusively with the homologous allergy-producing substance.

107. **Fixation of Mobilized Scoliosis and Kyphosis.**—Fränkel reports excellent results from treatment of curvature of the spine by a plaster bed holding the spine in extremely exaggerated over-correction, such as is obtained by the creeping

exercises which Klapp has found of such service in treatment of scoliosis. (His method of thus transforming children with deformed and weak backs into "back athletes" was described in The Journal, Feb. 24, 1906, page 625.) The creeping is the ordinary four-footed gait exaggerated to twist the spine from side to side in as wide sweeps as possible. Overcorrection by a plaster bed supplements the effects of the creeping exercises and renders the benefit permanent. In fitting the bed the aim is to utilize all the points where it is possible to obtain support, the head, shoulder, arms, pelvis and thighs all helping to maintain the over-correction. Especially important is it to fasten the swinging arm and swinging thigh as in the creeping exercise. Only by utilizing all the leverage points possible are the best results attainable. The plaster sheet is applied with the patient lying sprawled out on the table as in an exaggerated correcting creeping exercise, the head, chest and pelvis resting on supports to facilitate the application of the plaster, the arms extended and grasping supports at a certain distance above the table. The plaster bed for a patient with right convex dorsal scoliosis is shown in Figure 1, and for a left convex lumbar *scoliosis in Figure 2.* The combination of effectual and prophylactic functional treatment with a plaster bed constructed on the same principles is giving extremely gratifying results at the university clinic in Berlin in charge of Bier, where the method is being applied on a large scale. Fränkel is Bier's assistant.

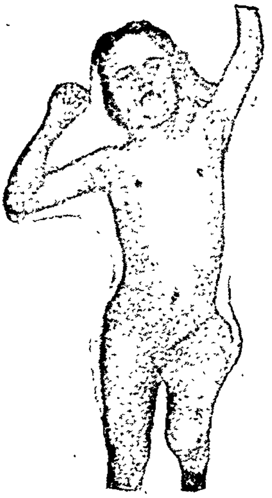

Fig. 1

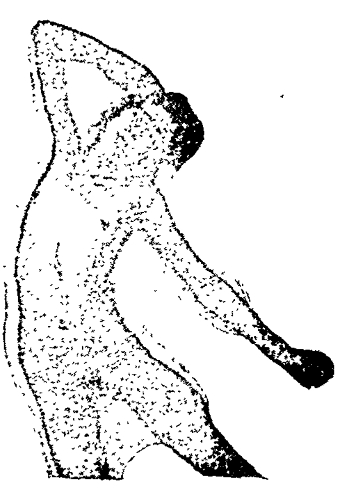

Fig. 2

108. **Phosphaturia.**—Schlagintweit discusses five types of phosphaturia, and remarks that both soft and hard alkaline concrements may be present for a long time without causing disturbances. He has had from 280 to 300 patients with phosphaturia, and has operated in nineteen or twenty of the cases. All his observation and research has but confirmed him in the opinion that phosphaturia is essentially a secretory disturbance in the kidneys of nervous character. The irritation causing the nervous disturbance may be at some other point of the urinary apparatus and act by reflex influences, or it may be due to a solitary functional anomaly in the kidney cells. That is to say, he regards phosphaturia as a local neurotic affection, and its *frequent connection* with neurasthenia, hypochondria, abdominal *atony*, *mental strain* and mania testifies further to this relationship. Boursier has reported a case of intense phosphaturia in a clergyman which subsided after correction of phimosis. Among the other evidences presented to sustain this view is the prompt elimination of large amounts of phosphates when the ureter catheter is introduced into a sound kidney pelvis, while the urine from *the other kidney contains* little, if any, phosphates, showing the influence on the secretory apparatus of the reflex stimulus from introduction of the catheter. If the urine is very alkaline and contains much phosphates, the indigo-carmin test may prove misleading, as the urine is liable to be colorless; addition of a little acid to the urine, however, counteracts the influence of the alkalies and brings out the blue tint at once. He warns, further, that a simple alimentary or neurotic phosphaturia may lead to ammoniacal cystitis or pyelitis. *Treatment of the phosphaturia* and its consequences must be both neurologic and gastro-intestinal. If no lesion can be found in the urinary tract, Schlagintweit gives hydrochloric acid internally and forbids all irritating and alkaline food and drinks. If he finds leukocytes in the urine, he alternates the hydrochloric acid with disinfectants for the urinary tract. If the phosphaturia still persists, he consults with a gastro-intestinal specialist or neurologist or both, bearing in mind that too much specialist neurologic and urologic intervention may breed serious neurasthenia. With a phosphaturic sexual neurasthenic the slightest heedless word or unnecessary instrumental meddling may avenge itself with grave consequences. The serious outcome possible with phosphaturia is instructively shown by his case of a well-to-do merchant of 39; phosphaturia developed after a gonorrheal abscess in the prostate, and for seven years he passed occasional phosphate calculi and had kidney colics, always on the left side. The pains were so severe be became addicted to morphin; then followed a period of four years free from concrements. Then the left kidney was removed, but the whole drama started anew *on the right side, with increasing morphin and cocain* addiction. Each puncture hole suppurated so that some abscess had to be opened nearly every day, and scarcely any part of the body was free from them until he succumbed. Phosphaturia is thus shown to be a subject interesting alike the practitioner, the internist, the stomach specialist, neurologist and surgeon.

129 Treatment of Typical Fracture of the Radius. M. Friedmann.

128. **Transient Blindness After Injection of Anesthetic into the Orbit.**—Woino reports a case similar to the one recently published by Kredel. He injected a 0.5 per cent. solution of novocain-suprarenin, according to Braun's technic, into both orbits in operating for a bilateral frontal empyema. The local anesthesia had been preceded by the *scopolamin-morphin* "twilight sleep." The solution evidently caused an inflammatory effusion in the orbit, mechanically disturbing the circulation in the optic nerve and leading to transient blindness, with congestion in the lids and some temperature. The symptoms soon subsided entirely so that vision was normal by the third day. The complete restitution excludes the assumption of a neuritis.

there was effusion in the abdominal cavity and signs of tuberculosis in the lungs, suggesting tuberculous ascites, and the pregnancy was artificially interrupted on this account, as the tuberculin reaction had been positive, but the course of the case revealed a gall-stone trouble with no further signs of tuberculosis. Each time, however, the uterus reacted to the three tuberculin injections with hemorrhage, but no trace of tuberculosis could be found in the uterus adnexa after their removal nor in the scrapings of the uterus. In another case the test injection of tuberculin caused such serious peritonitic symptoms with ileus and collapse that the patient's life was in danger. This case warns of the necessity for care in applying the tuberculin test when there are reasons for assuming the existence of adhesions between the intestines. Schlimpert and Zöppritz have also recently called attention anew to the unreliability of the tuberculin test in affections of the female genital organs. Franqué operates on principle whenever convinced of the tuberculous nature of a tumor in the uterus adnexa, *if it seems to be the only or the predominant manifestation of the disease.* He thus operated in thirty-seven cases over five years ago, including nineteen with genital and eighteen with peritoneal tuberculosis, and all the patients made a smooth recovery and were much benefited with a single exception. exercises which Klapp has found of such service in treatment of scoliosis. (His method of thus transforming children with deformed and weak backs into "back athletes" was described in The Journal, Feb. 24, 1906, page 625.) The creeping is the ordinary four-footed gait exaggerated to twist the spine from side to side in as wide sweeps as possible. Overcorrection by a plaster bed supplements the effects of the creeping exercises and renders the benefit permanent. In fitting the bed the aim is to utilize all the points where it is possible to obtain support, the head, shoulder, arms, pelvis and thighs all helping to maintain the over-correction. Especially important is it to fasten the swinging arm and swinging thigh as in the creeping exercise. Only by utilizing all the leverage points possible are the best results attainable. The plaster sheet is applied with the patient lying sprawled out on the table as in an exaggerated correcting creeping exercise, the head, chest and pelvis resting on supports to facilitate the application of the plaster, the arms extended and grasping supports at a certain distance above the table. The plaster bed for a patient with right convex dorsal scoliosis is shown in Figure 1, and for a left convex lumbar scoliosis in Figure 2. The combination of effectual and prophylactic functional treatment with a plaster bed constructed on the same principles is giving extremely gratifying results at the university clinic in Berlin in charge of Bier, where the method is being applied on a large scale. Fränkel is Bier's assistant.

108. **Phosphaturia.**—Schlagintweit discusses five types of phosphaturia, and remarks that both soft and hard alkaline concrements may be present for a long time without causing disturbances. He has had from 280 to 300 patients with phosphaturia, and has operated in nineteen or twenty of the cases. All his observation and research has but confirmed him in the opinion that phosphaturia is essentially a secretory disturbance in the kidneys of nervous character. The irritation causing the nervous disturbance may be at some other point of the urinary apparatus and act by reflex influences, or it may be due to a solitary functional anomaly in the kidney cells. That is to say, he regards phosphaturia as a local neurotic affection, and its frequent connection with neurasthenia, hypochondria, abdominal atony, mental strain and mania testifies further to this relationship. Boursier has reported a case of intense phosphaturia in a clergyman which subsided after correction of phimosis. Among the other evidences presented to sustain this view is the prompt elimination of large amounts of phosphates when the ureter catheter is introduced into a sound kidney pelvis, while the urine from the other kidney contains little, if any, phosphates, showing the influence on the secretory apparatus of the reflex stimulus from introduction of the catheter. If the urine is very alkaline and contains much phosphates, the indigo-carmin test may prove misleading, as the urine is liable to be colorless; addition of a little acid to the urine, however, counteracts the influence of the alkalies and brings out the blue tint at once. He warns, further, that a simple alimentary or neurotic phosphaturia may lead to ammoniacal cystitis or pyelitis. Treatment of the phosphaturia and its consequences must be both neurologic and gastro-intestinal. If no lesion can be found in the urinary tract, Schlagintweit gives hydrochloric acid internally and forbids all irritating and alkaline food and drinks. If he finds leukocytes in the urine, he alternates the hydrochloric acid with disinfectants for the urinary tract. If the phosphaturia still persists, he consults with a gastro-intestinal specialist or neurologist or both, bearing in mind that too much specialist neurologic and urologic intervention may breed serious neurasthenia. With a phosphaturic sexual neurasthenic the slightest heedless word or unnecessary instrumental meddling may avenge itself with grave consequences. The serious outcome possible with phosphaturia is instructively shown by his case of a well-to-do merchant of 39; phosphaturia developed after a gonorrheal abscess in the prostate, and for seven years he passed occasional phosphate calculi and had kidney colics, always on the left side. The pains were so severe he became addicted to morphin; then followed a period of four years free from concrements. Then the left kidney was removed, but the whole drama started anew on the right side, with increasing morphin and cocain addiction. Each puncture hole suppurated so that some abscess had to be opened nearly every day, and scarcely any part of the body was free from them until he succumbed. Phosphaturia is thus shown to be a subject interesting alike the practitioner, the internist, the stomach specialist, neurologist and surgeon.

128. **Transient Blindness After Injection of Anesthetic into the Orbit.**—Woino reports a case similar to the one recently published by Kredel. He injected a 0.5 per cent. solution of novocain-suprarenin, according to Braun's technic, into both orbits in operating for a bilateral frontal empyema. The local anesthesia had been preceded by the scopolamin-morphin "twilight sleep." The solution evidently caused an inflammatory effusion in the orbit, mechanically disturbing the circulation in the optic nerve and leading to transient blindness, with congestion in the lids and some temperature. The symptoms soon subsided entirely so that vision was normal by the third day. The complete restitution excludes the assumption of a neuritis.

142 Differential Diagnosis Between Gastric Cancer and Simple Chronic Gastritis with Achylia. S. Kemp. Concluded in No. 28.

138. **Trachomatous Urethritis?**—Heerfordt asks whether trachomatous conjunctivitis can be caused by modified gonococci and whether there is such a thing as a trachomatous urethritis, referring to Prowazek's "cell inclusions," and discussing the literature and findings on the subject, especially Hertzog's assumption that the cell inclusions are merely modified gonococci. Heerfordt thinks that the evidence to date sustains this view.

141. **Cancer in the Digestive Tract.**—Otto analyzes the findings during life and at necropsy in 196 cases of cancer in the digestive organs, studying especially the length of the period after the first symptoms were noted before the individuals applied for medical aid; also the survival and the causes of death. The tabulated details show that persons very seldom die from the cancer as cancer, but they succumb to perforation or hemorrhage or functional disturbance from compression. In fifty-four of the cases the first symptom had been trouble from stenosis or motor insufficiency in the stomach or intestine; in eight others perforation occurred without warning. Jaundice was the first symptom in a case of cancer of the duodenum, in two in the pancreas and four in the gallbladder; in fifty-four the first symptoms had suggested chronic gastritis, including eight cases of cancer of the pancreas and three of the esophagus; pains in the lumbar region had been the first symptom in five cases, the cancer being in the pancreas in all this group. There was evidently a longer or shorter period of latent development before the onset of symptoms. One table shows the conditions in regard to metastasis, glandular enlargement and extent of the cancerous involvement as compared with the number of days or months or years that had elapsed after the first symptoms had attracted attention. This interval had been from one to four years in two cases of cancer of the esophagus without metastasis, and in three with involvement of the regional glands, in four cases of cancer of the pylorus with involvement of glands, and in two in the intestines without metastasis. The cancer had not been diagnosed in fifteen of the total 196 cases, but in four of this group the intercurrent fatal disease had probably masked the symptoms. In thirty-three cases extensive malignant disease was found at necropsy within two months after the first symptoms. Of the total 196, 121 of the patients died within the first six months and the date is not known for nine others. These early fatal cases included thirty of cancer in the esophagus, eighteen at the pylorus, seven at the cardia and twenty-five in the body of the stomach. The length of the latent phase is determined mostly by the width of the organ involved—the narrower the lumen the sooner symptoms develop. Consequently, cancer in the stomach and large intestine may have a long latent period, while cancer at points easily obstructed, as at the pylorus, soon makes its presence felt. The early fatal outcome with cancer of the pancreas is due to the mechanical functional disturbances in the region. The chief aim for further study of cancer is, therefore, he says, the first period of latency before the malignant disease has reached the stage of obstruction and compression.

THE FUNDAMENTAL PRINCIPLES OF PEDIATRICS *

HENRY DWIGHT CHAPIN, M.D.
NEW YORK

Pediatrics, at present, may be divided into two parts; first, that relating to the treatment of disease and perversion of function; second, that concerned with the production of well-developed physique in children. More attention is usually paid to the first than to the second of these branches.

If its scope were broadened, pediatrics might be defined as that branch of science which concerns itself with the animal aspect of the production of human beings. This science could then be divided into two parts; first, that devoted to the production of the highest development of the human being as an animal; second, that concerned with the management of the growing human animal when malformed, or with perverted functions, or subjected to mechanical injury, or attacked by parasitic microorganisms, or poisoned. It is evident then, that the pediatrist should be versed in general biology, bacteriology, protozoology, chemistry and physics.

While the public is not yet fully educated to the advantages of consulting a pediatrist before children are sick, it would be to the advantage of children, of parents, and of the community at large if every child during its most active period of growth were supervised by a well-equipped pediatrist, meaning by this, one who has had a broad training in general science as well as in a special department of medicine. If a physician undertakes to look after the development of a child, he should thoroughly understand the broad principles of human development and of animal life in general; it is not enough simply to be able to follow the ideas of some prominent teacher or authority.

It would prove an advantage to all physicians if the fundamental principles of the management of infants could be firmly established and thus taken out of the field of discussion. In order to attain this result, it is essential that the teachings concerning the chemistry of feeding be in accord with the general science of chemistry, that the problems of infancy falling in the province of physics be recognized as such, and that the teachings concerning animal life and development be true to those principles which have been found to apply to life in all its forms.

While medical men stand well in the forefront when it comes to the relations of human beings and animals to bacteria and protozoa, it must be confessed that they often lag behind in respect to the general care, nutrition and development of the human being in relation to his environment. The physician may broaden out to advantage at the points where science at large touches these problems.

The life-cycle of human beings, like that of all forms of animal life, may be sharply divided into two periods: first, that in which all of the food is derived from the mother's body in specialized forms; second, that in which none of the food is obtained from the mother's body but a wide variety of forms is taken. It is during the period in which the mother secretes the specialized forms of food that the tissues are produced and become differentiated into organs. When the organs of nutrition are developed, such forms of food are no longer needed and the infant has become a living machine that is able from food to build the future adult. This living machine is operated on much the same principle as a mechanical engine. It takes in fats, sugars and starches, and, by combining them with air procured through the lungs, obtains a supply of energy. This energy, when expended, appears in the form of heat which must be removed as fast as it is liberated, and it is accordingly found that all animals are provided with two cooling systems. For ordinary conditions, radiation of heat into the surrounding air is sufficient, but when the temperature of the air is nearly as high as that of the body, or higher, radiation fails to cool sufficiently, and heat is removed by being changed into latent heat through the evaporation of perspiration.

An infant taking 36 ounces of breast milk daily receives food yielding about 792 calories, or enough heat to raise the temperature of a 14-pound baby 113 C. In other words, this food will liberate enough heat to raise the temperature of the infant above the boiling-point of water. It may easily be appreciated, then, how important is the proper working of the infant's cooling system; yet how few realize that infants and all animals have cooling systems, and that the life habits of many animals are largely controlled by them! Some animals of enormous strength, such as the lion and cat tribe, are incapable of prolonged effort because they cannot get rid of the heat liberated as fast as it is produced.

A large part of the sickness among infants in hot weather may be due to ineffective cooling of the living animal motor. Imagine an infant on a hot day lying in a crib surrounded by curtains. Air movement is stopped, and the atmosphere around the infant becomes so saturated with water vapor from the evaporated perspiration that no more can evaporate, with the result that the infant's cooling system breaks down and vomiting and diarrhea may ensue. Boiling water, and vapor from it, have the same temperature, 212 F., yet the vapor has absorbed almost one thousand degrees of heat and rendered it latent or insensible. As long as the air is not

THE FUNDAMENTAL PRINCIPLES OF PEDIATRICS *

HENRY DWIGHT CHAPIN, M.D.
NEW YORK

Pediatrics, at present, may be divided into two parts; first, that relating to the treatment of disease and perversion of function; second, that concerned with the production of well-developed physique in children. More attention is usually paid to the first than to the second of these branches.

If its scope were broadened, pediatrics might be defined as that branch of science which concerns itself with the animal aspect of the production of human beings. This science could then be divided into two parts; first, that devoted to the production of the highest development of the human being as an animal; second, that concerned with the management of the growing human animal when malformed, or with perverted functions, or subjected to mechanical injury, or attacked by parasitic microorganisms, or poisoned. It is evident then, that the pediatrist should be versed in general biology, bacteriology, protozoology, chemistry and physics.

While the public is not yet fully educated to the advantages of consulting a pediatrist before children are sick, it would be to the advantage of children, of parents, and of the community at large if every child during its most active period of growth were supervised by a well-equipped pediatrist, meaning by this, one who has had a broad training in general science as well as in a special department of medicine. If a physician undertakes to look after the development of a child, he should thoroughly understand the broad principles of human development and of animal life in general; it is not enough simply to be able to follow the ideas of some prominent teacher or authority.

It would prove an advantage to all physicians if the fundamental principles of the management of infants could be firmly established and thus taken out of the field of discussion. In order to attain this result, it is essential that the teachings concerning the chemistry of feeding be in accord with the general science of chemistry, that the problems of infancy falling in the province of physics be recognized as such, and that the teachings concerning animal life and development be true to those principles which have been found to apply to life in all its forms.

While medical men stand well in the forefront when it comes to the relations of human beings and animals to bacteria and protozoa, it must be confessed that they often lag behind in respect to the general care, nutrition and development of the human being in relation to his environment. The physician may broaden out to advantage at the points where science at large touches these problems.

The life-cycle of human beings, like that of all forms of animal life, may be sharply divided into two periods: first, that in which all of the food is derived from the mother's body in specialized forms; second, that in which none of the food is obtained from the mother's body but a wide variety of forms is taken. It is during the period in which the mother secretes the specialized forms of food that the tissues are produced and become differentiated into organs. When the organs of nutrition are developed, such forms of food are no longer needed and the infant has become a living machine that is able from food to build the future adult. This living machine is operated on much the same principle as a mechanical engine. It takes in fats, sugars and starches, and, by combining them with air procured through the lungs, obtains a supply of energy. This energy, when expended, appears in the form of heat which must be removed as fast as it is liberated, and it is accordingly found that all animals are provided with two cooling systems. For ordinary conditions, radiation of heat into the surrounding air is sufficient, but when the temperature of the air is nearly as high as that of the body, or higher, radiation fails to cool sufficiently, and heat is removed by being changed into latent heat through the evaporation of perspiration.

An infant taking 36 ounces of breast milk daily receives food yielding about 792 calories, or enough heat to raise the temperature of a 14-pound baby 113 C. In other words, this food will liberate enough heat to raise the temperature of the infant above the boiling-point of water. It may easily be appreciated, then, how important is the proper working of the infant's cooling system; yet how few realize that infants and all animals have cooling systems, and that the life habits of many animals are largely controlled by them! Some animals of enormous strength, such as the lion and cat tribe, are incapable of prolonged effort because they cannot get rid of the heat liberated as fast as it is produced.

A large part of the sickness among infants in hot weather may be due to ineffective cooling of the living animal motor. Imagine an infant on a hot day lying in a crib surrounded by curtains. Air movement is stopped, and the atmosphere around the infant becomes so saturated with water vapor from the evaporated perspiration that no more can evaporate, with the result that the infant's cooling system breaks down and vomiting and diarrhea may ensue. Boiling water, and vapor from it, have the same temperature, 212 F., yet the vapor has absorbed almost one thousand degrees of heat and rendered it latent or insensible. As long as the air is not saturated with vapor, or is nearly saturated, but in motion, this change from sensible to insensible heat takes place and it is perfectly feasible to be cool and comfortable in air whose temperature is above 100 F., provided this air is dry or in motion and thus capable of vaporizing perspiration. In fact, one can be kept quite cool by a current of hot dry air if a wet cloth is kept next to the skin.

---

* President's Address before the American Pediatric Society at Mohonk Lake, N. Y., May 31, 1911.

When an infant has been subjected to conditions such as render it unable to liberate its heat properly, the treatment that has proved most successful is to stop all food temporarily, thereby reducing heat production; to give the infant baths to remove heat; to keep it quiet to prevent the expenditure of energy which liberates heat; and to send it to the country where the air is cool or dry or in motion; then, unless there is very acute poisoning, recovery usually takes place.

No doubt bacteria play a large part in the summer sickness of infants, but as they are present in food at all seasons, it is evident that the heat gives them an advantage over the infant which they do not possess in cooler weather, or when conditions are favorable for the infant to rid itself of the heat. Restoring the infant to normal action causes the bacteria to lose their effect.

In hot weather food cannot be needed for its caloric or heating effect; it is required rather for its energy content, and the teaching should be in accordance with this fact. Feeding for energy is, to a large extent, a branch of physics; in the management of summer cases a knowledge of the principles of physics would thus often be of greater value than acquaintance with many of the drugs so often employed. The protein and mineral matter are for building materials and repair, and chemical composition is here the controlling factor, as far as potential value is concerned. It is, however, entirely out of place to value protein by its energy or caloric contents. What would be thought of an architect who determined the suitability of timber for a building by the amount of heat it would produce if burned? The feeding of energy and of building materials must be done with a distinct idea of the purposes they are to serve.

The emphasis on the necessity of plenty of fresh air should not be looked on as a hobby. The animal motor operates by a combination of oxygen in the air and the fats and carbohydrates of the food, and one is useless without the other. Insufficient air means incomplete combustion, and the products of incomplete combustion clog up the animal motor. Air is thus as essential as food.

In managing the nutrition of the infant much can be learned from general biology. In all forms of animal life the mother supplies specialized forms of food to the young until their digestive organs are developed, and no method of feeding that ignores this fact can be of the highest value. Many years ago I called attention to the fact that the protein of all milks has a developmental as well as a nutritive function. An artificial food for infants should contain the building elements and energy foods in about the same quantities as those in mother's milk if the best development is to result. Attention should likewise be paid to see that the food behaves in the stomach like mother's milk, but it will not do to compare foods by their chemical analyses alone, as it has long been known that two foods of the same chemical composition might not be interchangeable in nutritive value, and there are factors involved in feeding that chemical analysis cannot explain. The reason for this may be found in some of the later work in chemistry, as exemplified in the following illustrations: It is a curious fact that two clays, having the same chemical composition, may have entirely different physical properties, and that clay near the mouth of a river will have different properties from the same substance further up the stream, the two clays being derived from the same parent rock and having similar compositions. Acheson reasoned that this difference might be due to the fact that the clay down stream had come into contact with washings from organic matter, and by adding vegetable infusions to the upstream clay he was able to increase its plasticity and make it act like the clay down stream. Here is a practical illustration of what profound changes the most insignificant additions to a substance may produce. Bodies that are insoluble in water may be rendered soluble if certain foreign substances are present in the most minute quantities. Duncan gives the following illustration:

> The mere presence of a trace of a foreign body may make an insoluble body soluble. The following puzzling fact is known to but few: chromic chlorid is a curious substance that exists in two forms, soluble and insoluble. The insoluble violet crystals may be left under water for days unaffected . . . but drop into the test-tube a trace of chromous chlorid, even 0.000025 of a gram, and the violet crystals hasten to bury themselves in the water; the temperature rises and the indigo-blue liquid results. This is an example of what is called physical catalysis, for the chemical properties of the chromic chlorid are the same after as before; it has simply passed into solution. Turning now to chemical catalysis, we are confused by the number of examples, for, owing to the recent ferment of investigation, it would take a dictionary to chronicle them.

Remarkable results have been obtained in industrial chemistry by the use of such catalysts. Substances which have been obtained indirectly by the aid of plants can now be made artificially. Heretofore, when the necessary ingredients to form desired substances were brought together, they would not combine. There was something in the plants, however, that would cause such combinations to take place. Indigo has been obtained from the indigo plant, but it was found that the mere presence of a trace of copper or mercury would make the ingredients combine in the laboratory, and now it is made artificially. Platinum black is used to cause the ingredients of formaldehyd to combine, and other substances will cause metallic gold, silver, platinum and graphite to go into aqueous solution called colloidal solution.

How many factors in feeding may be influenced by such apparent trifles remain to be discovered, but that numbers of the vital processes are thus controlled is beyond doubt. Hunt makes the following statement:

> Diet has a marked effect on the resistance of animals to certain poisons; the resistance of some animals may be increased forty-fold by changes in diet. Certain diets, notably dextrose, oatmeal, liver, and kidney, greatly increase the resistance of mice to acetonitrile; their effect is similar in this respect to the administration of thyroid; the effect of an oatmeal diet in increasing the resistance of certain animals to acetonitrile is probably due, in part, to a specific effect of the diet on the thyroid gland; this is an illustration of how an internal secretion may be modified in a definite manner by diet. . . . The experiments show that foods such as enter largely into the daily diet of man have most pronounced effects on the resistance of animals to several poisons; they produce changes in metabolism which are not readily detectable by methods ordinarily used in metabolism studies. The ease and rapidity with which certain changes in function

are caused by diet are in striking contrast with the essentially negative results obtained by the chemical analyses of animals fed on different diets.

According to Alexander:

> Bald chemical analyses cannot express the digestibility and availability of a food any more than it can express or explain the action of the digestive juices or, in fact, any other physiologic process. In all these processes can be traced the influence of the colloidal substances, present in the body, whose effects are quite out of proportion to their small mass. As soon as we approach the chemistry of the living organism, we are confronted with problems of colloid chemistry, and there is no doubt but that a correct understanding and application of its principles will throw much light on many other obscure problems in biology, physiology and medicine.

These foreign bodies, whose mere presence causes such profound changes, are called catalysts and a peculiar property which they possess is that, at times, they lose their efficiency. When this occurs, they are said to be poisoned. After a time they may recover their power to produce the changes they formerly caused.

The question as to what this has to do with the practical management of infants may here be raised. McCullom conducted some experiments to see how simple in form the food elements could remain and still be combined in the animal body, it long having been believed that animals could not live for any length of time and develop on the pure food elements. Pure fat, sugar, starch, ash-free protein and the ash of milk were used, filter-paper being employed to give bulk. For a time there was gain, then a standstill and finally a loss. By adding successively such flavoring agents as cinnamon, celery, vanilla, caramelized sugar, distillate from strong cheese and salt, it was found that the loss could be prevented. Leaving the fat out of the food temporarily or changing its form, or altering the sugar content of the food, was found to improve the utilization of the food. "In one instance toward the end of the experiment, bacon fat, freshly rendered and filtered through paper, induced hearty consumption when every other means failed." His conclusions were as follows:

> Without palatability the ration may possess all the necessary food ingredients and yet fail to nourish an animal properly. The failure of previous efforts to maintain animals on a mixture of relatively pure, proximate constituents of our foodstuffs was due to lack of palatability of such mixtures. When sufficient care is given to changing the character and flavor of the food supplied in such simple mixtures, it is possible to induce an appreciable amount of growth.

Here is an illustration of the action of catalysts in practical feeding. One worked well until it became poisoned or lost its efficiency. A change in the form or flavor of the food brought another catalyst into action, and it in turn lost its efficacy. The beneficial effect of variety of diet has long been known, but the scientific basis on which it rested has not been suspected hitherto. We often get the same good effect by changing the flavor of the infant's food or by altering the form of the food elements, especially the carbohydrates.

Such facts as these could never have been explained by practical infant-feeding, or rather, the principles could not have been evolved; and this shows the advantage of being familiar with general science and applying principles worked out elsewhere to the management of infants.

That a profound change in the function of the human digestive organs may be brought about by changing the character of the food has been shown by Yakawa, who fed young men who had been vegetarians all their lives a diet composed largely of beef, milk, eggs and rice. The fats, and particularly the protein, were not well assimilated. There was loss of appetite, lassitude and constipation. Such a result is at variance with the belief held generally that animal protein is better digested than vegetable protein. But this case is an illustration of the biologic principle that all living things tend to adapt themselves to their food and environment. Those who have been trained to digest animal protein develop digestive organs well fitted for this purpose and digest it better than they do vegetable protein, and vice versa.

It has been said that one principle is worth many facts, for it covers them all. If the few main principles in pediatrics could be grasped, a large number of facts might be forgotten to advantage. Pediatrics cannot take the position it deserves, until those who practice it recognize that their work is to help infants adapt themselves to their food and environment, and this calls for at least an elementary knowledge of general biology, bacteriology, protozoology, chemistry and physics. We must broaden our scientific outlook.

Medicine has always advanced more rapidly as an art than as a science, partly because it has not been sufficiently rooted in the principles and methods of general science. The extreme growth and differentiation of specialism has here acted both as cause and effect. Ingenious and successful technic, rather than the more laborious and widely applicable study of underlying principles, has often satisfied. The specialties themselves have been accepted without much appreciation of their relative values. Those of fundamental importance are grouped with others having only local forms that minister to comfort and utility, but not often directly to life itself. It is thus right to make a distinction between a major and a minor specialty. Of the former, pediatrics should take the highest place, as it deals with the first and formative period of life, and consequently renders the most lasting service to the race. It is time that a new account of stock be taken of the various branches of medicine and that they be lined up with a truer perspective as to relative importance. Thus will the dignity and importance of pediatrics be made clear to the profession and the public. It offers to-day the most promising field for advanced work in scientific and experimental medicine. Fully to occupy this field, its followers must apply the general and broad methods of science at large to the solution of its problems.

One of the deepest sayings of Sir Francis Bacon was: "The end of philosophy is the intuition of unity." Let us apply this broad truth to science. The end and object of all science is the recognition of unity.

Primitive Man and Disinfection.—Man has an instinctive repugnance to all noxious odors, and from the earliest time has sought to mask their presence by the use of aromatic substances, says Dreyfus (*Jour. Am. Pub. Health Assn.*). The use of perfumes is probably a relic of the effort of primitive man to counteract this evil. Many religious ceremonies, such as the burning of incense, have also the same origin, and embalming as practiced by the Egyptians is a good example of successful attempts to arrest putrefaction in very early ages. Sulphur has been employed from the earliest times, and Homer describes its use in religious ceremonies. In the time of Hippocrates, sulphur was regarded as an antidote against the plague. Ovid makes mention of the fact that sulphur was employed by the shepherds of his time for bleaching fleeces and for purifying their wool from contagious diseases. During the plague of Athens, Acron, according to Plutarch, stayed the spread of the epidemic by lighting fires in the middle of the public places and in the streets where deaths had occurred; and the lighting of fires during times of plague has been customary until quite recent times.

NEW MECHANICAL DEVICES FOR CLOSING WOUNDS *

E. WYLLYS ANDREWS, M.D.

CHICAGO

Comparing the work in various clinics, it is found that some men suture wounds rapidly. Most men require a large percentage of the total time for final closure, and nearly all take longer for this step than they themselves realize or would believe unless they have been timed by the watch.

In a series of observations made for me on my own work and that of other surgeons, the time was found to be so unevenly divided that the internal operative work often was briefer than the elaborate wound closure. Thus the neat and rapid interior work was robbed of its chief value to the patient by prolonging the total operation and anesthesia.

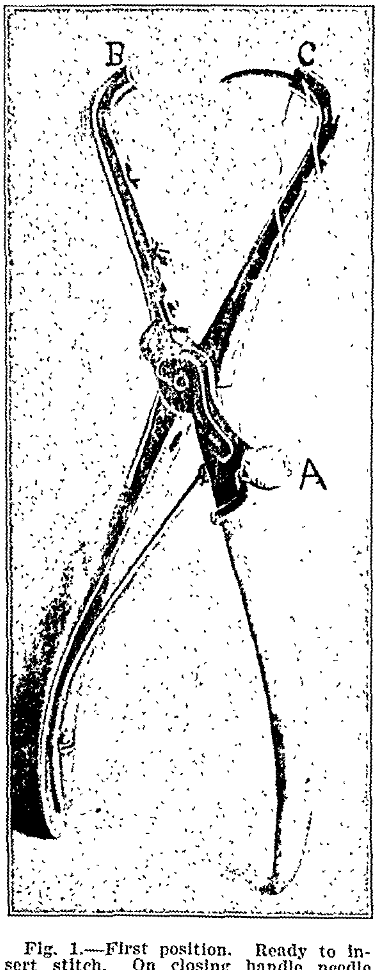

Fig. 1.—First position. Ready to insert stitch. On closing handle needle passes flaps and is seized automatically by opposite blade carrying thread through tissue. On pressing catch A needle is released at B and returns to C, ready for next stitch.

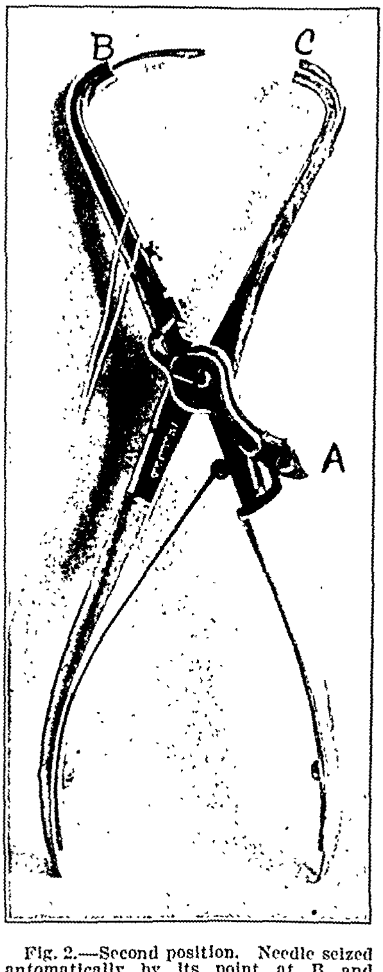

Fig. 2.—Second position. Needle seized automatically by its point at B and pulled through tissue by closing and opening handle. On pressing thumb catch A needle returns to first position, C.

Methods for hastening wound closure may be good or bad in proportion to their safety and nicety of adjustment, but they must not involve any sacrifice of the improved modern principles of anatomical restoration of layers whether in the extremities or the trunk.

On the other hand, if with equal security and asepsis wounds may be brought together in a briefer time or with more smoothness and less trauma, a new factor of safety will be added tending to the welfare of the patient.

Thus the use of Michel skin clips will shorten the time of a herniotomy or an appendectomy about five minutes. In spite of the fact that a few men can do the whole operation in that time, more men take fifteen minutes or longer, and some excellent operators would be surprised to be told that they take ten to twenty minutes by the watch for their careful wound closure. This is admirable from an anatomical standpoint. It is characteristic of some very conscientious workers and gives beautiful healing, but it is wrong to ignore the injurious effect of prolonging anesthesia even in simple cases.

On the other hand, in the very swiftest closure I have seen, as in the abdominal wall in laparotomies done with spectacular swiftness, I have been led to suspect that the suture work on the layers may have been slighted to gain speed. This may be unjust, since most of the very rapid work is done by men of enormous experience, but it is an inherent fault of hand suturing that it must be somewhat slow or else somewhat imperfect. Long practice with the needle gives speed, but only up to a certain point. To get beyond this point we must adopt new devices.

Reminding you again of the skin clips—five or six of them will close a three or four-inch opening in a quarter or half a minute. If we could only use them for all the layers, sixty seconds would be ample for a deliberate layer-by-layer closure of the abdominal wall. To make this possible, I have devised clips of absorbable metal for buried suture and for suturing blood-vessels, as described later in this paper. Before alluding to this, I wish to call attention to the possibility of sewing wounds by a machine.

For a number of years I have tried to perfect a sewing machine for wounds constructed with platen, fixed needle and bobbin or shuttle. In spite of the fact that several small hand and toy machines are made small enough to handle easily, none of them seems capable of being brought into cavities or depths of wounds or can be easily sterilized. These machines place only mattress stitches, whether one or two threads are used. They could not easily be adapted to overhand glover or interrupted stitching. After considerable discussion and study of the problem with the manufacturers of various machines, I became satisfied that we could never design a shuttle machine that would be anything but clumsy, heavy and inefficient, and therefore, dangerous about a wound.

It is different with forceps. With them we are familiar and know that we can place them in all sorts of deep and superficial locations even more readily than the hands or fingers. If forceps could be made automatically to insert stitches carrying threads by merely opening and closing their blades, we should combine some of the speed and accuracy of machine-sewing and the nicety and safety of hand-sewing.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

After some years of experimenting and disappointment, I have turned to forceps and needle as a *sine qua non* for surgical work, and have constructed several forms of forceps which will actually sew the skin and deep layers more smoothly and rapidly than by hand. Of course they are equally adapted for placing deep ligatures, single or multiple.

The object of these instruments is to gain speed, and, incidentally, regularity of spacing and of tension in the approximated edges. We must admit that this is as likely to be a drawback as an advantage. No machine can have the delicacy and tactile sense of the human fingers; but how much time can we afford to sacrifice for careful suturing by the fingers? Certainly in fine closure like the Lembert stitch in the hollow viscera it is invaluable. In external work, in which the fingers are little used, but mostly needle forceps, a machine sewed wound may well be neater and more delicately adjusted than one sewn by hand in equal time.

Classes of stitches better placed by machine than by the fingers or needle forceps are:

1. "Deep "suture ligatures," single or multiple, around vascular pedicles, as the mesentery meso-appendix, broad ligament, hernial sac, etc. In the depths of a wound or cavity with the sewing forceps one does not have to see the needle point. The forceps automatically and infallibly grasps it and draws it through. It is a particularly rapid method of cross-suturing a wide pedicle of any sort.
2. Straight lines of suture, in which accuracy of spacing, rather than accuracy of fitting, is desirable. Such wounds are abdominal incisions, both muscle-splitting and in the middle line. These are rarely closed now by single rows of deep stitches, but almost universally by anatomical restoration of the concentric layers from within outward. The suturing machine does this with a speed and accuracy far greater than the hand or needle-holder.

NEW FORMS AND NEW APPLICATIONS OF METAL CLIPS

The clips ("agraffes") used by Michel for the closure of the skin in mastoid and other operations interested me from the first. They seem to mark a new departure in methods of wound closure, and to open possibilities in several new directions.

When they were offered to the profession, I began to use them somewhat experimentally and with misgivings. Unlike most new appliances (especially mechanical devices) they proved a much more valuable device than even the inventor had claimed. From using them in a limited class of incisions, I learned to put them on almost every operative incision, either alone or in combination with some deeper stitches. I have, therefore, used many thousand of them in lieu of needle and thread closure for the skin. Experience with this method of approximation has resulted in an increasing appreciation of their value on the part of my patients, my assistants and myself.

It is true that my earliest experience was only with mastoid operations, but I learned almost accidentally that they were so neat, quick and painless in practical use, that they almost superseded other methods of skin closure in my work. I find that a number of American and European operators have made the same discovery, no doubt independently. While in some clinics they are not seen at all, a number of well-known clinics (as that of von Eiselsberg) employ them almost as a routine.

The advantages noted for the clips in our clinic have been:

1. Speed of application.
2. Asepsis.
3. Rapid healing.
4. Absence of pain.
5. Absence of scars.
6. Ridge-shaped or folded-up suture line.
7. No perforation of skin.

The only disadvantages I can imagine are:

1. Lack of strength.
2. Want of flexibility, causing pressure, irritation or ulceration.

These advantages and disadvantages may be considered in detail:

1. *Speed.* — Observations taken by my assistants showed from five to twenty minutes by various operators in closing ordinary operative incisions. In some instances this was as much as one-third or one-half of the time of operation. Several operators had methods of great nicety in skin-closure, but probably were not aware of the added time taken. The average time of closing (the skin only) by Michel's clips was fifty seconds for short incisions, such as hernia and appendix wounds.

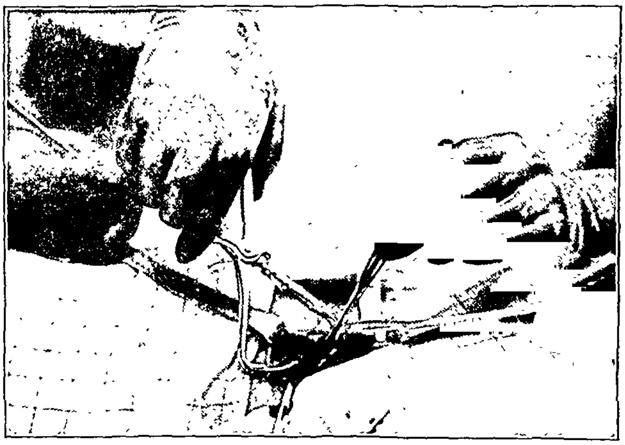

Fig. 3.—Closing abdominal wound (peritoneal layer).

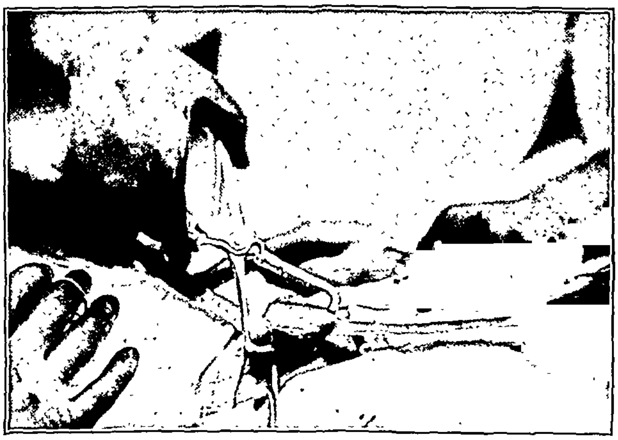

Fig. 4.—Closing abdominal wound (internal oblique layer).

2. *Asepsis.*—The occasional stitch abscesses due to buried catgut, to silkworm, silk, linen or horsehair, point to the fact that all methods which penetrate the ducts and follicles of the skin are subject to infection. This risk, it is true, is slight and is much minimized by our best modern technic, but is not wholly absent, because the deep layers of the skin are now known to be beyond the reach of our sterilizing agents, even of iodin. It is probable that our so-called aseptic wounds are examples rather of relatively light infections overcome by the tissues.

NEW FORMS AND NEW APPLICATIONS OF METAL CLIPS

The clips ("agraffes") used by Michel for the closure of the skin in mastoid and other operations interested me from the first. They seem to mark a new departure in methods of wound closure, and to open possibilities in several new directions.

When they were offered to the profession, I began to use them somewhat experimentally and with misgivings. Unlike most new appliances (especially mechanical devices) they proved a much more valuable device than even the inventor had claimed. From using them in a limited class of incisions, I learned to put them on almost every operative incision, either alone or in combination with some deeper stitches. I have, therefore, used many thousand of them in lieu of needle and thread closure for the skin. Experience with this method of approximation has resulted in an increasing appreciation of their value on the part of my patients, my assistants and myself.

It is true that my earliest experience was only with mastoid operations, but I learned almost accidentally that they were so neat, quick and painless in practical use, that they almost superseded other methods of skin closure in my work. I find that a number of American and European operators have made the same discovery, no doubt independently. While in some clinics they are not seen at all, a number of well-known clinics (as that of von Eiselsberg) employ them almost as a routine.

The advantages noted for the clips in our clinic have been:

1. Speed of application.
2. Asepsis.
3. Rapid healing.
4. Absence of pain.
5. Absence of scars.
6. Ridge-shaped or folded-up suture line.
7. No perforation of skin.

The only disadvantages I can imagine are:

1. Lack of strength.
2. Want of flexibility, causing pressure, irritation or ulceration.

These advantages and disadvantages may be considered in detail:

1. *Speed.* — Observations taken by my assistants showed from five to twenty minutes by various operators in closing ordinary operative incisions. In some instances this was as much as one-third or one-half of the time of operation. Several operators had methods of great nicety in skin-closure, but probably were not aware of the added time taken. The average time of closing (the skin only) by Michel's clips was fifty seconds for short incisions, such as hernia and appendix wounds.

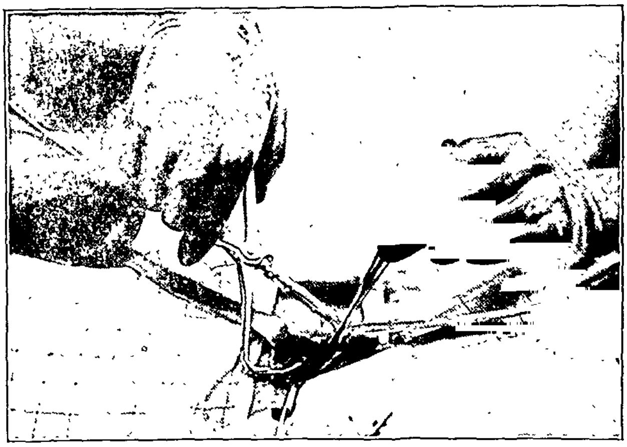

Fig. 3.—Closing abdominal wound (peritoneal layer).

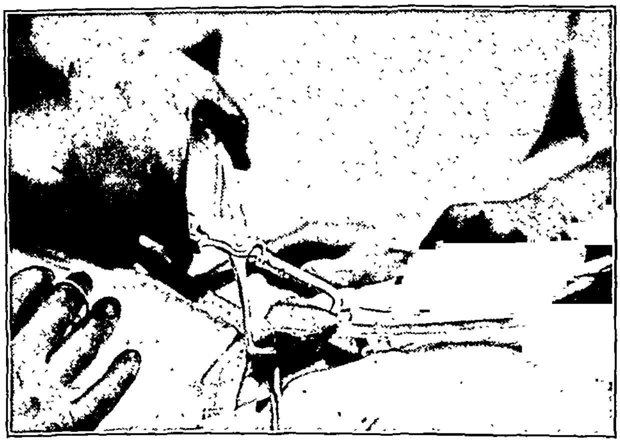

Fig. 4.—Closing abdominal wound (internal oblique layer).

2. *Asepsis.*—The occasional stitch abscesses due to buried catgut, to silkworm, silk, linen or horsehair, point to the fact that all methods which penetrate the ducts and follicles of the skin are subject to infection. This risk, it is true, is slight and is much minimized by our best modern technic, but is not wholly absent, because the deep layers of the skin are now known to be beyond the reach of our sterilizing agents, even of iodin. It is probable that our so-called aseptic wounds are examples rather of relatively light infections overcome by the tissues.

The clips, on the other hand, do not pass through the skin. Even should sepsis exist under their points, it finds no line of access as in the case of tissue traversed by a needle and thread. No method can be conceived more certain to vaccinate the deep layers with matter from the skin follicles than the puncture of a needle and the subsequent wiping of the tissues from without inward by the tight-fitting thread. It may be that the use of a double-needled thread, both needles being passed from without inward, would lessen this risk. As we always insert the figure-of-eight skin-fascia suture with two needles, this may explain a certain immunity we have had with it.

3. *Rapid Healing.*—The clips are removed early. Alternate ones in three days and the remainder in five days.

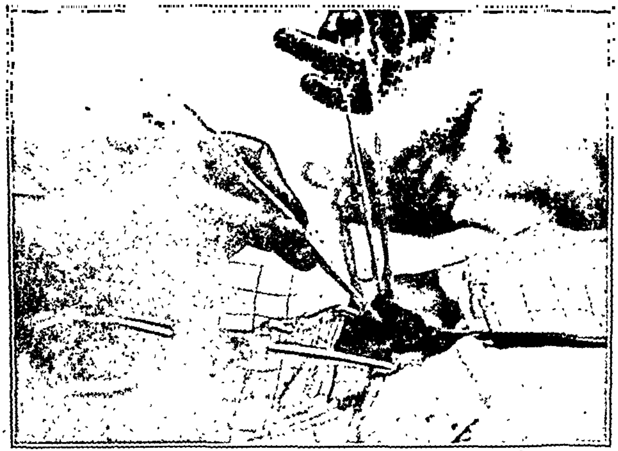

Fig. 5.—Closing abdominal wound (external oblique layer).

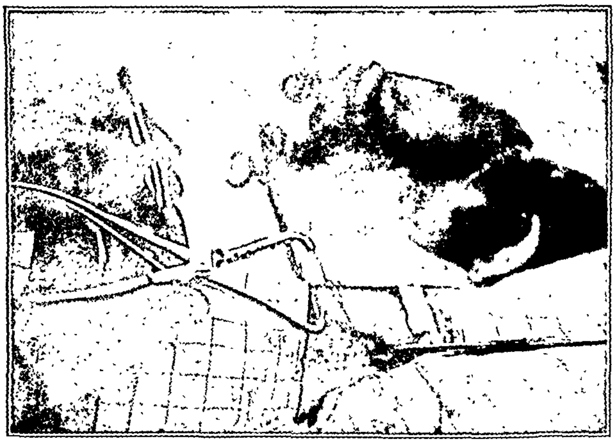

Fig. 6.—Closing abdominal wound (external oblique layer—unished suture).

4. *Absence of Pain.*—This is very noticeable. In goiter cases, hernia, laparotomies, etc., patients uniformly complain less than with sutures. The splint-like action and the absence of punctured wounds explains this. Without exception assistants and dressers report easy convalescence in these wounds.

5. *Absence of Scars.*—Early removal leaves no permanent marks. The clips, if left on too long, will, however, leave punctate scars like deep stitches.

6. *Ridge-Shaped or Fold-up Suture Line.*—This is a mechanical property of the clips and insures deep approximation, almost like that of two rows of stitches.

We turn now to the possible disadvantages above noticed.

1. *Lack of Strength.*—This may be a real limitation, but a desirable one, rather than an obstacle to the use of clips. They certainly lack strength in wounds under great tension, as in certain extensive breast amputations, in which approximation is difficult. They hold the skin and fat only, not the deeper fascia, but even with these obvious limitations they may well be combined with deep or buried retention sutures of any form. I sometimes have made the statement that the inability to hold skin under great tension was a virtue if it led us to avoid dangerous traction by suitable devices.

2. *Want of Flexibility.*—Metal clips are not flexible after once being applied, and hold the pinched-up skin rigidly. This will cause ulceration about as soon as a deep tense silk silkworm or wire stitch will; that is, in from eight to twenty days, but when clips are removed in five days, ulceration is never seen. No case of sloughing from pressure ever occurred in my use of them. I have always observed that a semi-rigid suture will cut less than a soft one. The splint action of a wire or silkworm gut is quite valuable, and this is one of the merits of metal clips.

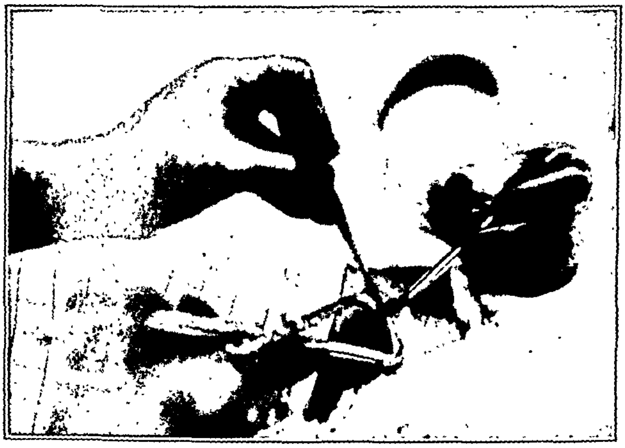

Fig. 7.—Closing abdominal wound (skin suture). One thread and needle used for the four stitch lines without knotting between.

In using Michel's clips I soon found great variations in the density and thickness of the skin of different parts of the body, which I had never noticed in using stitches. The skin of the epigastric region is at least twice as dense and thick as that of the appendix and hernia region. The imported clips are of just the right length to grasp the skin of the groin, neck, or that of the limbs, but not strong enough or long enough to hold well that of the epigastrium or hairy scalp; therefore, I have had made longer ones for these locations and smaller ones which I sometimes use for fine skin edges. I also found that in some cases quicker and more accurate application could be made by holding the larger clamps between the thumb and forefinger instead of with the Michel forceps.

Figures 8 to 11 show forms of thumb-clips which give quite as smooth and nice a cuticular junction as the Michel clip and are considerably stronger. One of the crescentic clips does the work of two of the smaller kind, so that a couple of them will close an ordinary 4 to 6 cm. incision; i. e., one requiring four small clips. It will be noted that the skin junction is held at twice as many points as the deep part, so that the line is ridge-shaped and held as if by a few deep and superficial stay stitches.

CLIPS USED IN HOLLOW VISCERA

The new feature which I wish to bring before you is the use of clips in intestinal work. In all locations permitting them to drop off into the alimentary canal they are safe and speedy of application. This precludes their use except in the inner suture of an anastomosis. They can be used on the mucous side, but not for the peritoneal, nor in place of the Lembert suture. These limitations do not prevent them from being of considerable utility in various ways about the intestine.

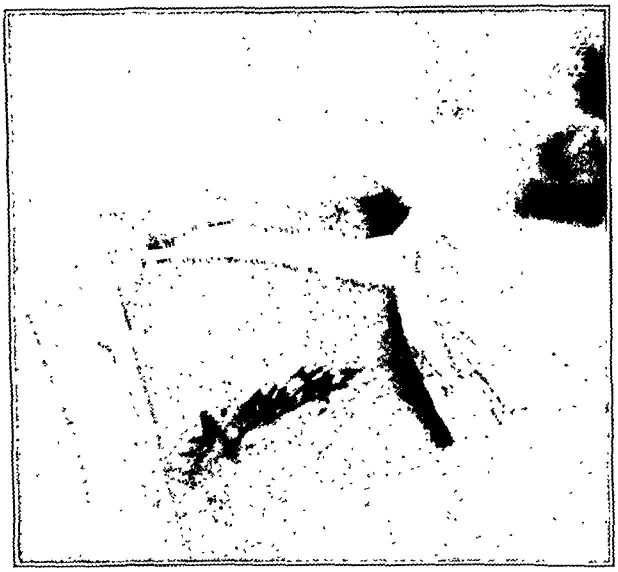

Fig. 8.—Author's wide clips, after type of Michel clip or "agraffes."

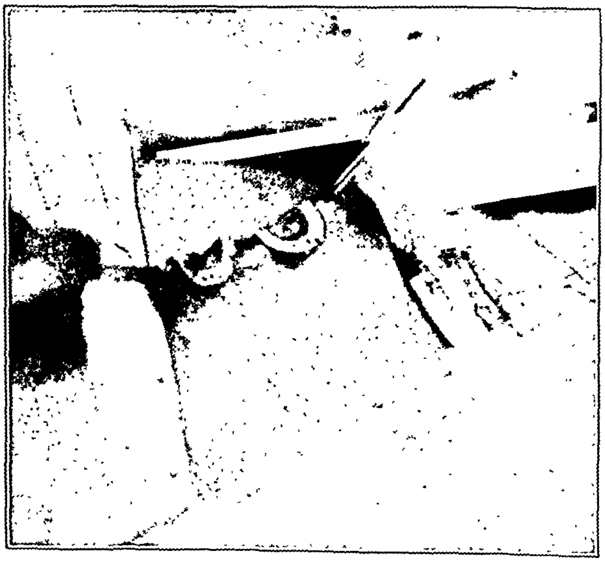

Fig. 9.—Author's horseshoe or double clips. Can be applied by thumb and forefinger or by forceps.

When an open gastric or intestinal approximation is made, the inner or deep suture is usually of strong silk or linen.

In doing such work I often put a clip on each end to mark out the inner or deep stitch-line. This seems to render the rest of the suture work easy and quick.

In the illustrations such use of the clips may be observed.

CLIPS USED FOR HEMOSTASIS

Finally, I must add that as a substitute for artery forceps and ligatures, I find the small clips of great value. Their action is clamp-like and they check oozing promptly, either interstitial or from large branches. I have found this of great value in the abdomen, throat and brain, as it does away with numerous dangling forceps. The objection to leaving small staple-like foreign bodies in wounds and cavities is slight in comparison with their advantages. No objection at all exists in cavities like the intestine, rectum, or vagina, where, as in hysterectomy, they are far easier of application than forceps or ligatures.

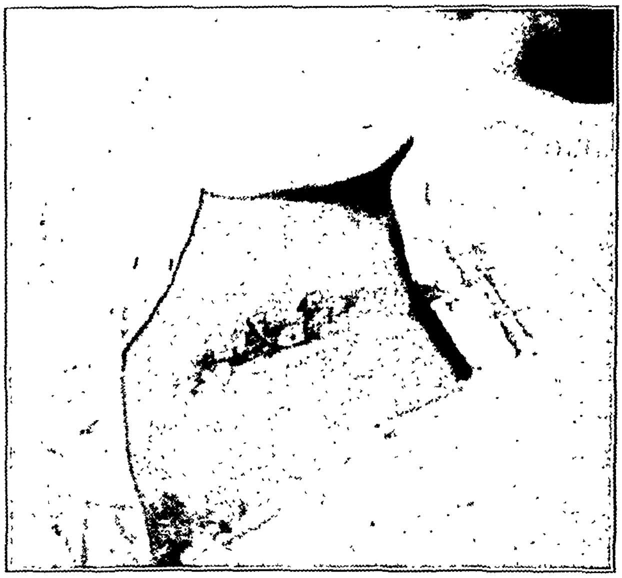

Fig. 10—Author's horseshoe clip. One drawback to this form is a tendency to slip or ride too high from edge of wound.

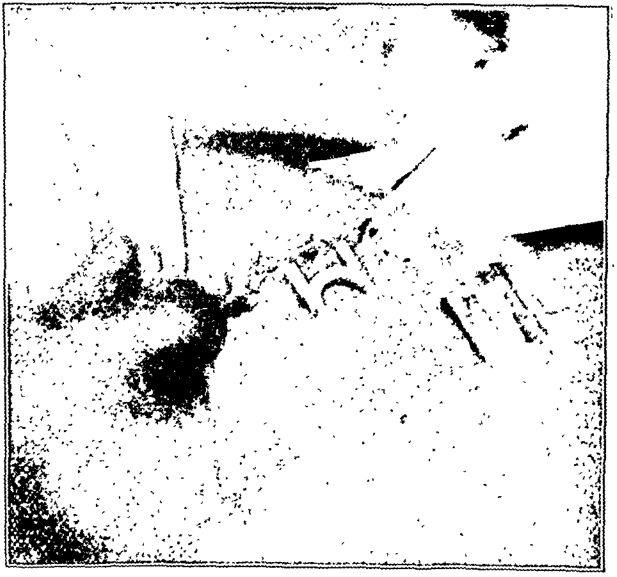

Fig. 11.—Author's double square clip. Has fine teeth, 1 mm. long, at tips to bite into cuticle.

The metal used for outside work is German silver. Copper, brass and block-tin do not, in my work, give the right degree of softness combined with firmness after bending. They must have no elastic tendency to spring open after clamping into place.

To secure absorption of the little metal staples after placing deep in wounds, I tried aluminum, zinc and magnesium. The latter is ideal in being quickly absorbed, but is so brittle that it breaks instead of "clinching" or crimping together when clips and staples are made of it. I am now using an alloy of these metals, which is tougher and promises well for rapid absorption.

I shall report on this material when I have had a longer series of operations under its use. With a good absorbable metal clip the deeper layers of a wound can be closed and buried, giving all the speed of external clip closure and supplanting the thread and needle at all stages.

32 North State Street.

GONORRHEAL OSTEOPERIOSTITIS OF THE LONG BONES *

STEPHEN H. WATTS, M.D.
Professor of Surgery in the University of Virginia
CHARLOTTESVILLE, VA.

Although gonorrheal osteoperiostitis of the epiphyses, and especially of the small bones of the hands and feet, is not very uncommon, this is far from being true of osteoperiostitis of the diaphyses of the long bones; in fact, no mention is made of this condition in the usual text-books and systems of surgery, and its existence has even been disputed. In the following case, which I shall describe in some detail, the femoral diaphysis was very extensively involved.

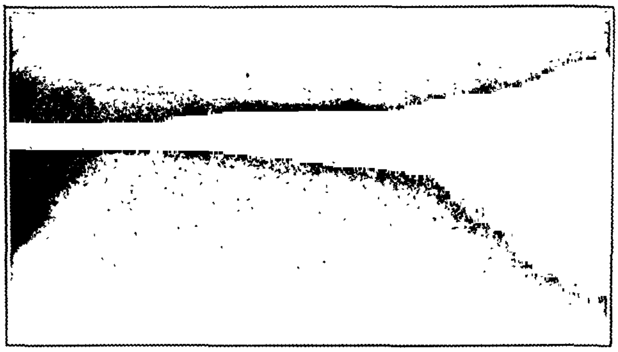

Fig. 1.—Definite deposits of new bone about femur, seventeen days after operation.

Patient.—J. M., aged 24, was admitted to the Johns Hopkins Hospital, January 2, 1907, complaining of an abscess on the left thigh.

History.—The family history and previous personal history were unimportant. There was no history of gonorrhea before present attack. The present illness began two weeks ago with swelling in the left thigh, which became painful, hot and hard. There was no history of injury. On account of inability to use the leg, the patient remained in bed for a week previous to admission. His appetite was lost, bowels became constipated and he had night sweats. He did not know that he had any fever. He dated the illness from a gonorrheal infection of four weeks' duration, the discharge continuing until one week before examination. A bubo developed on the left side but disappeared without discharging.

Examination.—Patient was a healthy-looking boy, in good general condition. Temperature was 103.6 F., pulse good volume and tension, 90 to the minute. Leukocytes 12,400. Examination of heart, lungs and abdomen negative. The patient had an acute urethritis up to one week before examination when the discharge ceased; he had a purulent balanitis, gonococci being found in pus about the glans penis. The glands of the groin were slightly enlarged, not tender. Prostate rather tender. Over the anterior and outer aspects of the middle third of the left femur there was a tender indurated area 10 by 14 cm. in diameter, apparently an abscess beneath the quadriceps muscles. The surface temperature was elevated but the skin was not reddened. The hip and knee seemed to be in nowise involved.

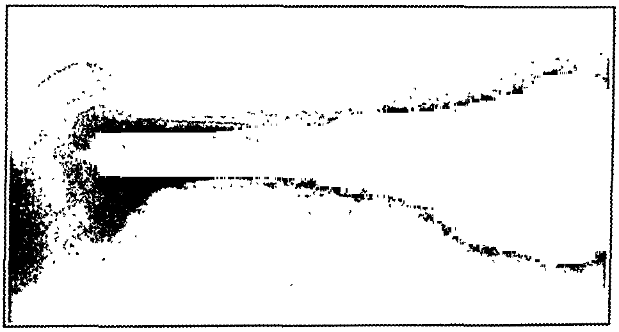

Fig. 2.—Thick envelope of new bone about femur, thirty-seven days after operation.

Operation.—Jan. 2, 1907, an incision 14 cm. in length was made over the swelling on the anterior and outer aspect of the thigh. The muscles were separated and the swelling found to be due to a small collection of fluid beneath the periosteum, the fluid being turbid but not actually purulent. A pure culture of the gonococcus was grown from this fluid by Dr. Rufus Cole, now of the Rockefeller Hospital, New York. The periosteum was very thick, edematous and lined by a velvety granulation tissue. It had been stripped away from the bone over a considerable area by the collection of fluid beneath it. The exposed bone was slightly roughened by deposits of new bone. The marrow cavity was not opened. The wound was irrigated with mercury bichlorid and packed with iodoform gauze.

Pathologic Examination.—Sections of the thickened periosteum were examined by Dr. W. G. MacCallum, who made the following note: "The section shows some new-formed bone embedded in a great deal of very vascular granulation tissue. Outside of this there is muscle, the individual fibers of which are separated by the same vascular granulation tissue. The interstices of this tissue contain much fibrin, and there are very abundant wandering cells which are as a rule not polymorphonuclear leukocytes, but mononuclear cells of various sorts, many of them with long branching protoplasmic bodies. The new bone is in the form of anastomosing laminæ, only partly calcified and thickly surrounded by osteoblasts. About these masses, and in the meshes, there is a vascular granulation tissue filled with cells indistinguishable from the osteoblasts and in places continuous with them, otherwise the tissue resembles that seen in any other granulation formation.

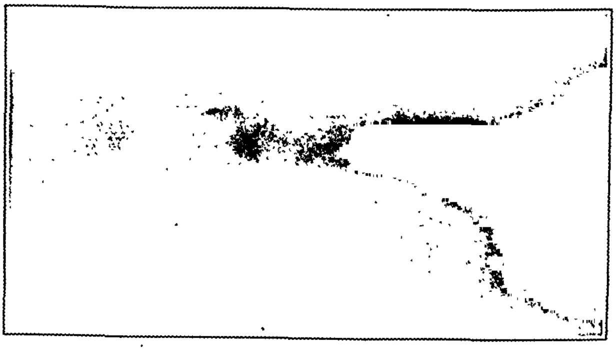

Fig. 3.—Great thickening of femur, eight months after operation.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

No definite organisms can be seen in the specimen stained with methylene blue."

Course.—Jan. 19, 1907: General condition of patient is not very satisfactory. He looks rather pale. Temperature ranges between normal and 102. Pulse is of small volume, rather low tension, ranging around 100 to the minute. The heart sounds are clear. The wound was dressed to-day. There was a small amount of purulent discharge. The whole left thigh is considerably swollen and there seems to be a distinct thickening of the femur, beginning a short distance below the greater trochanter and extending almost to the condyles. The whole extent seems somewhat tender but the most tender points are on the outer side of leg, 6 to 8 cm. below the upper border of the trochanter and on the inner side, a short distance above the knee. Movements of hip and knee are free and painless. A skiagraph (Fig. 1) was taken and this shows definite deposits of new bone about the femur.

Jan. 27, 1907: Condition of patient is much improved. He eats well and sleeps much better than formerly. For the last few days he has complained of no pain. Temperature seems to be subsiding gradually. The highest point in last three preceding days was 100.6 at 8 p. m. yesterday. The wound was dressed to-day. There was a small amount of purulent discharge. The wound cavity still extends 10 to 12 cm. along the bone, which is exposed throughout this extent. The thigh is less swollen but the bone seems thicker than ever. Tenderness has all disappeared. Movements of hip and knee are perfectly free and painless.

Feb. 10, 1907: Patient is now feeling very well and wants to walk. Temperature is about normal. Wound is clean, granulating well. There is still a considerable area of exposed bone in the bottom of the wound. Movements of hip and knee are perfect and painless. There is a marked thickening of the femur. Skiagraph taken a few days ago (Fig. 2) shows a thick envelope of new bone about the shaft of the femur, extending from a short distance below the trochanter, almost to the condyles. No pain or tenderness is anywhere present. On palpation the femur seems to be about 9 cm. in diameter. Circumference of left thigh at its middle is 37 cm., right thigh 32 cm.

Feb. 20, 1907: Patient has been walking for several days. The leg has given him no pain. Temperature has not been elevated. The left femur is still greatly thickened. The wound is entirely healed. The patient is discharged from hospital.

He was seen again on Aug. 31, 1907, when his general condition was found to be good. Examination of the leg, however, revealed a great thickening of the femur. There was still a small sinus near the middle of the old scar. *X*-ray was taken (Fig. 3) and showed an enormous thickening of the entire femur.

After this the patient was lost sight of and has not been seen since. It would be interesting to know whether there was any infection of the marrow cavity, and if so, whether it was sufficient to so impair the blood-supply of the cortex as to cause sequestration. I am inclined to believe that there has been no sequestration of the femur in this case.

According to Hirtz,[1] Fournier, in his remarkable study appearing in 1869, first established definitely the clinical existence of periosteal manifestations of gonorrhea. He distinguished periostitis and periostosis, the former being simple inflammatory deposits in the periosteum, the latter being tumors resulting from infiltrations between the bone and periosteum. He insisted on the much greater frequency of periostitis, which produces slight circumscribed, ephemeral swellings, most frequently found on the tibia just above the insertion of the sartorius, on the lower extremity of the humerus, on the upper end of the fibula, on the greater trochanter of the femur, on the posterior surface of the os magnum and on the extremities of the metacarpal and metatarsal bones. The only symptoms are a more or less acute pain in a circumscribed area with perhaps a little edema and redness of the overlying skin. Liable to recurrence at each reinfection, they can at times proceed to the chronic stage and produce a periostosis, which is flat, fixed, hard and adherent to the bone, usually small in extent, but capable of a considerable development.

Fournier and most other authors who, following him, have studied the subject, have emphasized the purely periosteal origin of the lesion, its epiphyseal location and its frequent association with the deforming variety of gonorrheal arthritis.

Achard and Hirtz have, however, in recent years called attention to the fact that the deforming variety is not the only form of gonorrheal rheumatism which is accompanied by lesions involving the bones; moreover, they insist that the diaphysis as well as the epiphysis may be involved and that the bone itself as well as the periosteum plays a part in the process. Achard observed a young woman, who, following a non-deforming gonorrheal arthritis of the left knee, had a marked general thickening of the left femur, which he considered to be undoubtedly due to a hyperostosis. The case of Hirtz was that of a young girl, aged 19 years, who, in the third month of gonorrheal rheumatism, presented a marked swelling of the lower two-thirds of the right femur. The swelling was very indolent, developed insidiously and was discovered accidentally. The bone seemed double its normal thickness and the consistency of the tumor was such as to suggest an hyperostosis, even though the skiagraph showed the part played by the bone itself to be comparatively slight. As to the gonorrheal nature of the condition, he thought there was no doubt, coming on, as it did, in the course of a bad gonorrheal rheumatism, while the arthritis of the right knee still persisted and a vaginal discharge was present; moreover, there was no evidence of syphilis, hereditary or acquired.

While admitting that the inflammation may extend from a gonorrheal joint along the adjoining long bones to a greater or less extent, Durand and Nicolas[2] are doubtful regarding the actual involvement of the periosteum and bone, and are inclined to think that the thickening, which we make out in these cases, is due to an inflammatory infiltration of the tissues outside of the periosteum.

They assert that, inasmuch as they can find no account of an operation or autopsy performed on the bone, the exact nature of such cases is not known, but, granted that a periostitis or periostosis does exist, they think the process cannot be compared to that of an osteomyelitis, since there is no suppuration or sequestration.

According to them, there are no osteoperiostitic changes, but an inflammatory induration which is in the neighborhood of the bone without really altering its elements and in no case would anything seem to show the existence of an osseous lesion. In the absence of anatomic demonstration it would seem to them that neither the clinical nor radiographic signs can be considered convincing. On clinical examination they find simply a deep swelling or tumor, usually limited to the vicinity of the joint, but able to extend more or less along the diaphysis; there exists, however, no sign which permits them to say definitely that the bone or periosteum is involved; moreover, they state that no *x*-ray has shown indisputably the presence of any alteration in the bony substance.

In support of this view, they report a case of acute gonorrhea with suppurative gonorrheal arthritis of the right knee, in which there was great edema of the right leg and thigh, most marked near the knee. Later on, examination showed a hard thickening above and below the knee, which the authors considered to be due to an infiltration of the soft parts and not to a periosteal thickening, as the skiagraph showed no bony changes, and the induration and thickening gradually disappeared.

[2] Durand and Nicolas: Sur l'ostéopériostose hypertrophiante blennorrhagique des grandes os des membres, Lyon méd., 1907, cix, p. 693.

My case and others in the literature, however, show that the gonococcus can produce marked changes in the bone and periosteum. I cannot speak authoritatively regarding the exact nature of the thickening and induration about the long bones in the neighborhood of gonorrheal joints, but I am inclined to think that in the majority of these cases, the bone and periosteum are not involved, while in some there is probably a definite osteoperiostitis.

We are all familiar with the cases of exostosis of the os calcis of gonorrheal origin, described by Jacquet,[3] on the posterior surface of the bone beneath the tendo Achillis, and by Baer,[4] Durthe and others, on the plantar surface of the bone at the origin of the flexor brevis digitorum. Four of the five cases operated on by Baer were examined bacteriologically and in three of these gonococci were demonstrated. It seems to us that these are clearly cases of gonorrheal osteoperiostitis.

Cases of supposed gonorrheal osteoperiostitis of other bones have been observed by Claisse and Ozenne.

Claisse[5] reports the case of a girl, aged 19, with gonorrhea, in whom a persistent pain, increased by sudden movement or pressure, appeared about the costal cartilages, soon followed by the development of a series of nodosities in this region, suggesting a gonorrheal rosary. The gonorrheal origin of the lesions was not definitely demonstrated by bacteriological examination.

Ozenne[6] describes the case of a man, aged 25, who had a definite gonorrhea, which was apparently cured. Shortly afterward, apparently without traumatism, a pain appeared in the lower portion of the right leg and a swelling was found on the anterior and internal aspect of the leg, three finger-breadths above the ankle. The skin over the swelling was slightly reddened and the surface temperature elevated. Over the lower end of the tibia the swelling was well defined, hard, flat and immovable. Although gonococci were not demonstrated by incision, Ozenne considered this to be a case of gonorrheal periostitis with tenosynovitis of the extensor tendons of the foot. The swelling disappeared gradually without treatment other than a compression bandage.

Gonorrheal osteomyelitis is a very rare condition, though theoretically it is hard to understand why it is not as frequent a complication of gonorrhea as arthritis. I have been able to find only two definite cases in the literature.

Ullman,[7] in 1900, reported the case of a man, 27 years old, who in the third week of a second attack of gonorrhea had a chill which was soon followed by pain in both elbows. The lower end of the left humerus became greatly swollen and tender, and the skin over it reddened. A diagnosis of acute osteomyelitis was made and at the *operation a considerable amount of pus was found in the* marrow cavity. Gonococci, unmixed with other organisms, were demonstrated in the pus. Ullman thinks that if we took a careful history, as regards gonorrhea, in cases of osteomyelitis and tried to grow the gonococcus on the proper medium, we would find more of such cases to be gonorrheal in origin.

Heymann[8] has reported the case of a man, aged 40, who had had several attacks of gonorrhea, the last attack being about a year before admission. When seen by Heymann in September, 1908, he had had a cold for fourteen days, and during this time micturition had been painful. On examination he looked sick and feverish, and there was a slight urethral discharge, though gonococci were not surely demonstrated. The prostate was swollen and tender. On pressure the swelling of the prostate largely subsided, but the patient soon had chills and fever, which indicated, according to Heymann, that the emptying of the prostatic abscess had forced some organisms into the general circulation. After ten days the fever disappeared, but four days later the patient complained of pain at the lower end of the left tibia, and a tender, swollen area was found in this region. Conservative treatment failing to give relief, operation was performed. The periosteum was found to be stripped away from the bone and there was a small collection of pus beneath it. Pus was found in the marrow cavity and gonococci demonstrated in it.

Cupler's[9] patient, a young man with acute gonorrheal urethritis, developed an arthritis of the left shoulder. The joint was aspirated and 20 c.c. of fluid, containing gonococci, was removed. Failing to relieve the pain, the joint was opened the following day, a few cubic centimeters of fluid being found in the joint. There was a cavity in the head of the bone containing necrotic material, and smears made from the contents of the cavity showed the presence of gonococci. In this case, however, it cannot be said whether the bone or joint infection was primary, and I am inclined to believe that the bone involvement was secondary to that of the joint, as erosions of the bone are not infrequent in gonorrheal arthritis.

As I said at the outset, the literature concerning gonorrheal bone lesions is very meager, and, inasmuch as my case is the only one I have been able to find in which the *x*-ray has shown a marked thickening of the diaphysis, as the result of a gonorrheal infection, I have felt justified in putting it on record.

The Spirit of Research.—The investigator, says Professor Cannon in *Science*, is first of all one who thinks as much of what we are ignorant of, as he does of what has already been made clear. His chief interest is in the territory which has not yet been traversed. Indeed, he is to be classed with explorers and pioneers. For such men the complacent contemplation of things accomplished is intolerable—they chafe under the routine of established ways and find the satisfactions of life in adventures beyond the frontiers. Harvey, among the first of modern discoverers, expressed the spirit of research when he wrote: "It were disgraceful, with this most spacious and admirable realm of Nature before us, and where the reward ever exceeds the promise, did we take the report of others on trust, and go on coining crude problems out of these, and on them hanging knotty and captious and petty disputations. Nature is herself to be addressed; the paths she shows us are to be boldly trodden; for thus and whilst we consult our proper senses, from inferior advancing to superior levels, shall we penetrate at length into the heart of her mystery.

AIMS IN MEDICINE *

CHARLES F. STOKES, M.D., LL.D., D.Sc.
Surgeon-General, U. S. Navy
WASHINGTON, D. C.

William Paul Crillon Barton was graduated from Princeton College in the class of 1805. It was the custom at that time for each member of the class to assume the name of some celebrated personage; young Barton adopted that of Count Paul Crillon, and the initials " P. C." were retained by him through life.

He took his degree in medicine at the University of Pennsylvania, where he studied under the direction of his uncle, Dr. Benjamin Smith Barton, graduating in the class of 1808. His thesis on "Nitrous Oxid" was considered a classic for many years.

After an internship in the Pennsylvania Hospital, he was appointed a surgeon in the Navy in 1809. In July, 1811, just 100 years ago, the Secretary of the Navy, Mr. Paul Hamilton, directed Surgeon Barton to outline a plan of organization for the Medical Department, to be presented to Congress for approval. It may be justly said that Barton was the father of the Medical Department of the Navy.

Professor Holland, in his admirable history of the Jefferson Medical College of Philadelphia from 1825 to 1908, states that, in the summer of 1826 Dr. William P. C. Barton was appointed to a new chair of materia medica, and we find later on, when the Bureau of Medicine and Surgery was created in the Navy Department, the same William P. C. Barton occupying the office of Chief of Bureau, in reality the first Surgeon-General of the Navy.

Surgeon Barton published an account of the outlining of his plan for the organization of the Medical Department of the Navy, and modestly said that his schemes were thrown together with such order and system as was permitted by the limited time he had to devote to the subject under the pressure of professional duties on shipboard. He stated that the report containing his plans was certainly less perfectly digested and more carelessly treated than the importance of the subject demanded, because it was written during a tempestuous voyage from Norfolk to New York in the sloop-of-war *Hornet*, with the ever-to-be lamented Captain Lawrence, under the disadvantages, too, of seasickness and acute mental affliction from the recent loss of a friend.

In a foot-note he speaks of his friend Lawrence in the following terms:

> At the mention of the name of a man, dear to every American, and whose patriotism and valor are deeply registered in our memories, I hope I shall be excused in giving way to an impulse of feeling by declaring that, in sickness and in sorrow, I found in this magnanimous hero a comforter who administered the sweetest solace with even feminine tenderness; such were the superior virtues of a man who was gigantic and valorous in war.

Surgeon Barton was a prolific writer, devoting much attention to botany in connection with materia medica.

The dedication of his treatise on the internal administration of government and naval hospitals is as follows:

> To the Flag Officers, Captains and Surgeons in the Navy of the United States:
>
> A NAVY—rendered glorious by the brilliancy of its achievements and which has added luster to the nation, given dignity and importance to its character abroad:
>
> A NAVY—to the seamen of which, by their prowess and their victories, the skilful, the valorous, and the hitherto unconquered naval sons of Britain are forced to yield the palm of superiority:
>
> A NAVY—thus eminently distinguished even in infancy, and which has conquered its way to public favor and estimation: This attempt to promote its interests is most respectfully dedicated by the author.

In his concluding remarks in this treatise, Dr. Barton has to say the following:

> In the foregoing pages I have been necessarily led into the exposition of many and palpable abuses in the Medical Department of the Navy. There are not a few persons with whose interests such an exposition will very much interfere; from them, therefore, I expect no thanks; on the contrary, I look for caviling and censure at their hands. I am, however, prepared to meet it.
>
> My independence in expressing my sentiments on points of duty while in the Navy procured for me not a few enemies; but while I regret this consequence of a line of conduct that thrice the inconvenience could not have made me forego, I have the consoling assurance of having acquitted myself in the way of duty to the entire satisfaction of officers with whom I have served, whose regard and good opinion were of moment in my estimation.
>
> Both my feelings and my fortune have suffered by the determination I made when I first entered the service, from the execution of which I never in a single instance swerved, to pursue that line of conduct that I deemed consistent with the faithful performance of my duty and my trust, however such conduct might clash with the private or public interests of others, or differ from the customary proceedings of persons similarly situated with myself.

Such were the sentiments of the man who had most to do with formulating the plan of organization of the Medical Department of the Navy and whose name appears in that brilliant and courageous group of original professors who have made possible the great institution of learning from which you graduate to-day.

Your present faculty is built of precisely the same timber, and in seeking the personification of the highest aims and ideals in medicine I heartily commend their characteristics to your most careful study. I am proud to bring to your notice the close intertwining of the roots of origin that have since grown into the two great medical organizations—Jefferson Medical College and the Medical Department of the Navy.

Since 1842, when Dr. Barton became Surgeon-General, your alma mater has given us no less than 100 medical officers, and among them are names that have helped to make naval history in the past and are adding further laurels to medicine in the Naval Service to-day. I am proud to tell you that the last commission signed by the President is now in possession of a graduate of Jefferson and a former intern of your hospital.

Is it at all surprising that the mere mention of the name of your great institution of learning should awaken sentiments of affection, esteem and respect in the Navy? I can assure you that the great honor and privilege your board of trustees has conferred on the Medical Corps in inviting its ranking officer to address you on this occasion, has in nowise lessened this warm spirit of fraternalism.

As you go forth to-day after four years of association in lecture rooms, laboratories, hospitals and elsewhere, each inspired with a resolution to solve the problems that lie before him in accordance with the high standards in which you have been so thoroughly drilled, the conviction will be brought home to you that these problems have taken on a new and very personal form calling for the development of a resourcefulness and an individual effort that had not been exacted before. Your bearing and conduct in meeting these new responsibilities, even at the outset of your careers and in every hour of every day thereafter, will determine largely the measure of success that will be accorded you in the future.

---

* Valedictory address delivered before the graduating class of Jefferson Medical College, June 5, 1911.

You have chosen the grandest profession of them all, without exception, one demanding courage of the highest order, sacrifices without end, a profession little appreciated and less materially rewarded for what it has accomplished than any of the others.

It is well for you at this time to endeavor to develop proper aims and adopt high ideals to guide you in your every-day life, so that the impulse to act squarely and properly to yourselves, your patients and your community will be involuntary and unhesitating.

It has been well said that he is best educated who has the largest and most manageable series of orderly and useful habits in the storehouse of his brain and other nerve-centers. These habits include and cover what are ordinarily understood to be facts as well as reasoning and action. That brain is best equipped which, on the greatest number and variety of occasions in life, acts in a fairly automatic manner in the best way for the usefulness and happiness of the individual. Such a personality not only has the highest order of education, but also has the largest development of character in its broadest sense.

In his essay on two kinds of conscience, Norman Bridge has given us much food for thought and a guiding hand in the selection of high aims in medicine in its relations to individuals and its activities in the community.

He defines conscience as that governing principle, that guide of action, which gives a standard of conduct and judgment to every man. Conscience is largely a matter of education; to some degree it is inborn and, therefore, instinctive; applied to things, beliefs and principles, it is substantially all acquired. In order better to understand the many phases of human conduct, Bridge has described two kinds of conscience; one he has called the personal, or individual, conscience, the other the company, class or collective conscience.

The individual standard is perhaps the higher. It is this conscience that impels man to do what he alone believes to be right. It is the conscience of solitude and tranquillity—of man communing with himself.

The collective, or group, conscience is the standard of the community, and is an altogether different standard from the personal one. The two are often in conflict, although often completely in accord. The feelings and emotions of this standard are in general the ever-present emotions of mankind. All must act outwardly, at least, with slight variations, for the benefit of the race. The collective or group conscience is the executive or official conscience.

It is the personal or individual conscience that tends to impel the soldier, when first under fire, to flee. The group conscience, which has been developed by training and discipline, holds him in ranks with his fellow combatants.

The personal, or individual, conscience has had much to do with the great advances, the epoch-making stands taken by individuals. For instance, Ambroise Paré, the great French surgeon, was ridiculed and called an impostor when he advocated the ligature for arresting hemorrhage, to replace such barbarisms as the routine use of boiling oil and the actual cautery. John Hunter was accused of wasting his time in studying with painstaking care the growth of a deer's horn, but it was this study which led to a knowledge of collateral circulation and emboldened him to ligate the main vessel in aneurism. Harvey spent eight long years of investigation and research before he published his views of the circulation of the blood, which led to his being discredited, and it was fully a quarter of a century before this established scientific truth became generally recognized.

The difficulties of Jenner were even greater than those of Harvey, and, judging from certain well-meaning but misguided efforts that are being made strenuously to-day, not all are yet convinced of the efficacy of vaccination against small-pox. The pendulum has swung the other way, and the tendency now is hysterically to grasp the latest thought or idea, claiming vastly more for it than its originator proposed, only to meet with disappointment and discredit where both are unnecessary.

It is the group conscience, on the other hand, which rules the mob. A normal development of the two kinds of conscience to meet the vicissitudes of various situations leads to the most satisfactory results. In caring for an individual ill, the dictates of the personal conscience should be yielded to; when the welfare of a community is at stake, the promptings of the collective conscience should govern. In a military establishment the individual, or personal, conscience and its promptings are subordinated to the dictates of the group conscience, and this is justified by the objects and aims of such an establishment.

Surgeon Barton's activities and reforms were impelled by a pronounced development of the individual conscience and their beneficent effects are felt to this day.

The internal dissensions and difficulties with which Jefferson College was beset in its early days, as recorded by Professor Holland, resulted from too much personal conscience, and a neglect of the collective standard. With the establishment of a normal balance between the two began a progress almost unparalleled for brilliancy.

Let us see how the cultivation of these two kinds of conscience, in their proper proportions and relations, will guide us to a wise selection of our aims in medicine. The proper development of the personal conscience will make impossible commercialism, the dividing of fees, and other growing abominations of the day. The welfare of the patient will be our immediate consideration; his personality will receive the close study it merits, and we shall not be treating disease, as such, with the possible future applause of the medical society, or the allurements of a statistical report, before us. We shall not be wholly engrossed with the laboratory findings or the pathologic report.

Our diagnoses will not be made in the laboratory and in the *x*-ray room. The internist will not be found temporizing and unduly postponing the summoning of the surgeon with the misleading notion that he is practicing conservatism. Often bold, timely operative procedures are of the highest type of conservatism, in that they may not only save life and safeguard organs that would otherwise have become involved, but they may lead to a restoration of function with a minimum of aftereffects that delay would have made quite impossible.

The cultivation of that conscience that comes of a man communing with himself will lead us faithfully to train every sense with which God has blessed us, to develop manual dexterity, a touch of gentleness with strength and precision that will be recognized at once by our patients. Sight, hearing, smell and taste should not be neglected. Bandaging to-day is almost a lost art; the study of the mechanics of internal medicine and surgery has not received the attention its importance merits. How often do we find the narrowing of an outlet, a sluggish muscular wall or an inconsequent deformity of the foot, for instance, inducing conditions of such gravity that the slight and often perfectly remediable mechanical defect is quite lost sight of!

The enormous importance of the laboratory and its brilliant achievements in medicine are fully appreciated, and due credit is accorded the courageous minds that have evolved and demonstrated theories and facts that stand out as the milestones of real progress in the advance of medicine toward the goal of exact science.

Among the unfortunate consequences of this great advance is the dwarfing of the purely clinical side of medicine. The impulse to turn to the laboratory for the diagnosis, and afterward to try to fit the laboratory findings to the individual before us, is undoubtedly the tendency of the day. We should center on our patients at the bedside the closest kind of study, and let there be, *if necessary,* a tentative diagnosis, turning to the laboratory, afterward, for a confirmation, or a refinement of our conclusions. On the other hand, if we are not well trained clinically we should be quite at a loss if we found ourselves, perchance, beyond the comforting reach of the Roentgen-ray apparatus, and the diagnostic and therapeutic laboratory.

What bearing has the development of the so-called crowd or collective conscience on our aims in medicine? Let us see. With the growth of this standard the appalling record of 600,000 lives sacrificed annually in this country to preventable diseases would soon dwindle into comparative insignificance; there would be undoubtedly to-day a department of health with a representation in the cabinet, and the proper institution of sanitary administrative methods would yield in our civil communities the brilliant results that have followed these methods where the medical officers of the Army and Navy have been permitted to carry them out, hampered possibly only by insufficient funds, or the military features of the situation.

It is more than probable that this crowd conscience will be developed, as it should be, only when its importance to the masses is brought home to them on a dollars-and-cents basis. The lack of the so-called executive or collective conscience in these United States is not only amazing—it is appalling. The fact that this great country has no exhibit at the International Exposition of Hygiene, in Dresden, now in session, is perhaps not fitting for me to comment on.

You hear young men say that medicine is overcrowded and that so much has been accomplished that there is little left to be done. Should there be no further discoveries, or advances, in medicine and surgery from now on, and we were permitted to make use intelligently of the facts now in hand, the achievements of preventive medicine, administrative sanitation and bold surgical conservatism would startle the world.

The crimes of commission that find their way to our criminal courts sink into insignificance when compared with the grave crimes of omission and their far-reaching, direful consequences which we, in hardened indifference, take as a matter of course. Here is an almost untouched field. Results can come only, however, from an awakening of the crowd conscience through education, team work and convincing demonstration.

An example of the beneficent effects of the collective conscience is seen in the boards of trustees, guilds, societies and organizations that make possible our great hospitals and educational institutions. These splendid citizens often contribute liberally in a financial way and bring to bear their business training and administrative ability, to say nothing of time and painstaking labor, in this field of work. They should share with us the honors that may come to us, for they have made possible what measure of success may be ours.

President Taft showed thorough appreciation of this most excellent type of citizen when he eulogized recently the man who contributed to the revolutionary cause, without hope of reimbursement, $650,000—an enormous fortune for those days. Such as he made the success of our arms possible, and great sacrifices of this sort merit recognition along with the actual achievements of war. Those who by their sagacious activities awaken and keep alive intelligent patriotism, thus making possible an approach to preparedness when the horizon is not darkened by war-clouds, should be classed with the great leaders of peace times. The pseudo-patriotism and hysterical outbreaks that often come with the declaration of war are out of time and out of tune, and while ostensibly well meaning, are of little account.

The activities of physicians in civil life are almost entirely along humanitarian lines, while in the Army and Navy humanitarian considerations are of secondary importance, military duties being paramount. To understand properly the necessity for this subordination of the humanitarian aims of medicine, it will be well to outline some of the unusual features of the fighting establishments, and the Navy will serve admirably for the purpose.

The Navy is manned, equipped, organized and maintained to fight. The fleet is the Navy. The development of the highest type of fighting efficiency in the fleet should be the aim of all concerned. This problem is decidedly more intricate and difficult than is generally realized, both inside and outside the service. The battles of the future will no longer be the battles of brawn; they will be the battles of brains and they will be won by the combatant showing the highest development along this line. Science has taken a hand, and in the front rank we find specialized medicine, chemistry, mathematics, mechanics, physics and many scientific offshoots so harnessed, adapted and molded as to make possible a grade of military efficiency that was scarcely dreamt of a decade ago. Consider for a moment what the development of electricity has accomplished; what chemistry has contributed in the way of powder alone; what oil as fuel will do!

Each new activity brings to bear on the personnel new influences often seriously damaging to efficiency. It is of the greatest military importance that the medical department should not only familiarize itself with these scientific specialties and be prepared to repair the damage to the personnel from their employment in the fleet, but what is still more important, it must prevent and actually is averting this damage.

Side by side stand the lieutenant and the surgeon; the one by drilling and discipline striving to attain a high grade of efficiency, the other, who has selected at the recruiting station the physical type best fitted to meet the peculiar requirements, watches intently for effects that are likely to impair efficiency. For example, recently, on an endurance run, thirty odd men, utterly prostrated, were carried out of the fire room of a ship.

What was the cause of this serious breakdown in the personnel? Was it due to excessive heat, to contaminated air, to improper food or water? Or was it due to the assignment to duty in the fire room of a type physically unsuited to the arduous exactions of that station? These are the questions that would naturally come to the mind of an alert medical officer, and it is along these lines that the Bureau of Medicine and Surgery is bettering conditions.

The activities of the medical department are by no means confined to the personnel. The plans of new ships are always referred to the Surgeon-General before they are finally approved by the Navy Department. It is his duty to give them careful study, recommending such changes as in his opinion will keep the physical make-up of the personnel at the highest pitch, and at the same time will in no way impair the fighting possibilities of the ship. These recommendations are not in any sense prompted by humanitarian considerations; they are made solely to promote and maintain military efficiency.

What is the character of the personnel with which we have to deal? Let us consider two types of officers, the two whose duties and responsibilities are more closely allied than any of the others—line officers and medical officers.

The line is recruited from all over the country, from practically every grade of society, who, after passing rigid professional and physical examinations, begin a four years' technical course at the Naval Academy with an additional two years spent at sea, before they are finally commissioned. During the four years at Annapolis, the highest aims of their profession are instilled into them, such as discipline, honorable dealing, manliness, physical and moral courage, a proper conception of duty and its responsibilities, loyalty and patriotism and a willingness unhesitatingly to make that greatest of all sacrifices for their country's sake should occasion demand it. This splendid spirit was highly developed in that superb soldier, the late Captain Capron of the Army, who, on hearing that his son, a Rough Rider, had been wounded during the battle of San Juan Hill, in which both had been engaged, sought him out to find him lying dead at the roadside. Brushing back the hair from his brow, he scanned the features, strong even in death, and said, patting him affectionately on the head, "Well done, old fellow."

The development of this splendid spirit is by no means confined to the line; it underlies and guides the activities of the entire commissioned and enlisted personnel of the Navy.

The Medical Corps is the only branch of the service which may select its own personnel. Not only must a candidate be a graduate in medicine, but he is required to have served in a great civil hospital and present a diploma as a guarantee of the character of this service, before he is eligible to examination for a commission as assistant surgeon. An examining board then passes on his physical and professional qualifications, and if he meets the requirements, he is commissioned and enters the Naval Medical School, where he is taught the military features of his duties and is given special training to fit him for the great responsibilities of his new career. He is required to pass still another examination on the completion of this course, when he is assigned to the fleet for duty.

To have the right to wear the uniform of the United States Navy to-day is one of the greatest honors that can come to any of us, and that uniform which bears the insignia of the Medical Corps, with all it implies, is without a peer in the service. It is hoped that you will carefully consider these facts in choosing your life work in medicine

And what of the enlisted personnel? With the passage of masts, spars, sails and wooden ships went much of the romance of the sea, and along with the rest that faithful, resourceful type, the old-time sailorman. He is but a memory to-day, having been replaced by the alert young seaman-mechanic. The pace, with its complicated responsibilities, became too fast for the old fellows, and they have dropped out of the race completely.

In the Atlantic Fleet on its round-the-world cruise the average age of the enlisted personnel was about twenty-one years, on hearing which some humorist remarked that the Navy was manned by boys.

In order better to understand this new-type seaman-mechanic, let us look into a turret and see him actually at work. There are innumerable other situations in the complex make-up of a battleship that might be selected, still the turret will perhaps serve our purpose as well as any.

Side by side within this armored citadel lie the breeches of two monster 14-inch guns. The guns with their crews are separated by an incomplete partition or bulkhead, thereby stimulating a spirit of rivalry between the two gun-crews. There we see the turret officer, the turret captain, the gun-pointers and the crews. Gold lace has given way to dungarees; the cap alone distinguishes the commissioned officer—the men are nude to the waist. Each man is at his station, forming an unbroken chain from the gun to the magazine below with its tons of powder and shell.

The range of these guns is some 14 miles; the projectile, propelled by the burning of 350 pounds of powder, weighs 3/4 of a ton, costing about $500 for a single discharge. The monster blast is likely to destroy all unprotected ear-drums within a given zone, at the same time liberating gases poisonous in the extreme, so much so that, in one ship in which artificial ventilation was maintained during battle, several men were found unconscious in a single compartment into which the blowers had driven these noxious fumes.

From the fighting top comes a message to the central station in the bowels of the ship; a calculation is hastily made and directions are sent out to the turrets. The guns are trained accordingly; the gun-pointer picks up the enemy with his telescopic sight; the cross-wires are on him, the order to fire rings out, the gun is discharged and mathematically there should be a hit. We have, however, a personal element to take into consideration.

The picture is inspiring. The perfect team-work, the silence, the earnestness of great purpose written on each face strikes even the casual observer. The hazards of the situation are fully appreciated by all, yet the very dangers tempt those of the proper make-up for a fighting organization to seek these assignments. By constant drilling, mutual dependence, and perfected discipline the chances of mishap become very small; yet one weak link in the chain may instantly hurl all into eternity and perhaps destroy the ship.

What part does the medical officer play in all this? It is his duty to weed out the physical weaklings, or build them up, to safeguard these picked men from disease, to eliminate those whose nervous make-ups unfit them for this kind of duty; in other words, he has before him not only a study of the gross physical features of the personnel, but their psychologic characteristics as well. Let us center on the gun-pointer. If this man is of a high-strung nervous type, or has "too much" education, it has been found that, when the cross-wires of his telescopic sight are on the target, his alert mind is centered on the possibilities of the ignition of 350 pounds of powder at his side, and the chance for a hit has slipped by. His personal conscience has failed to be subordinated to his crowd conscience as it should be in this situation. It has been found that the use of telescopic sights at drills has in many instances seriously impaired the vision of these men. This break in the chain is of serious moment and is receiving the careful study its importance merits. The constructors may give us stability, the engineers high speed, the ordnance officers effective rifles and the commanders maneuver with consummate skill, still if the gun-pointers cannot see straight we are not going to have hits and the outcome of battle might hinge on this defect.

It is believed that the next naval battle between powers of the first class will last less than thirty minutes. By that time either the one or the other combatant will probably be annihilated or the supply of ammunition exhausted. The wounds of naval warfare are peculiarly destructive—lacerating tissues, splintering bones, killing outright—and are attended with profound shock; practically all are infected from the start. What are the aims of the medical department during battle? They should be military absolutely; humanitarian activities, although greatly to be desired, have no place in this situation, might even lead to additional casualties and possibly the failure of our arms.

At the close of battle the activities of the medical department at once become humanitarian, and our efforts are often exerted, not only in behalf of our own wounded, but in behalf of those of the enemy as well.

At this point the heretofore diverging paths of civil and military medicine are reunited on humanitarian grounds under the beneficent influences of the red cross. Our military efforts may lead to broad humanitarian results in making victory more decisive, thus entailing fewer casualties, and, further, the war itself may have been waged by reason of inhumanities which would cease with the success of our arms. The humane treatment of prisoner-patients of war by medical officers, before and after hostilities have ceased, is a potent factor in reestablishing friendly relations afterward.

Concentration in the past on the purely military features of the fleet has led to a one-sided development with a neglect of the humanities of naval warfare that would have made possible a breakdown in the medical department, the most appalling in history.

I have devised a plan which will, with the establishment of the Naval Medical Reserve Corps, efficiently attend to all our humanitarian responsibilities, and which bids fair to revolutionize this feature of naval warfare, giving to the wounded the highest type of surgical care from the firing-line until they are finally disposed of, and this they surely merit; it is in this field of work that I shall one day turn to you, my respected colleagues, for support.

In addition to the complex responsibilities of naval medicine, outlined, I fear, at too great length already, are the duties that go with service in the field which are precisely the same as those of the Army, except that they are naturally not quite so extensive. There has been no war in recent times, however, in which the navies of the world have not taken part in operations on shore.

The proper equipment and execution of these multifarious activities have led to the establishment of great supply depots, hospital and supply ships and the like; there are over 2,000 individuals serving in and under the medical department of the Navy to-day.

A word in conclusion as to what is done along humanitarian lines. Each ship has its sick-bay which may be likened to an army post hospital, and there are some fifty odd ships in commission.

The hospital ship *Solace,* equipped with 200 beds, with facilities equaling those of your metropolitan hospitals and carrying a number of skilled specialists, is serving with the Atlantic Fleet. There are nineteen general hospitals in commission, some of them among the largest and best equipped in the country, with six more building, constituting one of the largest hospital organizations in the world. We attend as well the large body of civil employees at navy yards and stations and the inhabitants of our island and outlying possessions. In this humanitarian field of work our aims and activities are precisely the same as those of civil practitioners, with the added interest of service in Alaska, Japan and the tropics.

From what has been said it is plain to be seen that in the Navy certainly the personal conscience must be subordinated to the collective conscience, and humanitarian aims give way to the military, up to a given point, at least. The medico-military duties referred to necessitate a profound study of all activities connected with naval warfare, in order to implant in the service, intelligently and effectively, what scientific medicine, in all its ramifications, has to offer to enhance military efficiency. It gives me great pleasure to express my unqualified appreciation and gratitude to the many skilled specialists in civil life, and, particularly, to the Faculty of Jefferson Medical College, for the painstaking, patriotic assistance they have unfailingly given us in our efforts to accomplish this great work.

If a single individual within hearing of my voice, or elsewhere, is helped in the choice of his aims and ideals in medicine, or in any other calling—if he is aided in any measure to the development of such a proportion between his individual conscience and his collective conscience as to lead to personal success and broadened public service in the community in which he resides, I shall feel fully recompensed for the effort that has been made.

SOME TENDENCIES IN MEDICAL EDUCATION IN THE UNITED STATES [*]

THE PASSING OF THE INFERIOR MEDICAL SCHOOLS

If you compare medical education in the United States twenty years ago with what it is to-day, you cannot help but be impressed with the remarkable change which has taken place. The period has witnessed a reform which is noteworthy in history. During the past decade, especially, there has been a steady decrease in the number of inferior medical schools and an elevation of standards in the better schools. The country has passed rapidly from a stage in which the proprietary medical school was dominant to one in which all, or nearly all, of the better medical schools are the medical departments of universities.

THE PASSING OF THE INFERIOR MEDICAL SCHOOLS

If you compare medical education in the United States twenty years ago with what it is to-day, you cannot help but be impressed with the remarkable change which has taken place. The period has witnessed a reform which is noteworthy in history. During the past decade, especially, there has been a steady decrease in the number of inferior medical schools and an elevation of standards in the better schools. The country has passed rapidly from a stage in which the proprietary medical school was dominant to one in which all, or nearly all, of the better medical schools are the medical departments of universities.

---

* Based on remarks made at the convocation exercises at McGill University, Montreal, June 5, 1911.

* Owing to the lack of space this paper has been reduced nearly half. The unabridged article is printed in pamphlet form and will be sent by the author, or by THE JOURNAL, on receipt of a stamped directed envelope.

It was not easy to bring such a change about. Every reform entails hardships; attempts at betterment invariably excite some animosity and antagonism. It says much for the spirit of the men in the medical profession and in the faculties of the medical schools that the majority of them have kept in mind the welfare of the profession, of medical education and of human service, and have been so ready to sacrifice their private interests when such self-denial was demanded.

[The author then discusses: (1) The reduction in the number of medical schools; (2) the increased requirements for admission; (3) the elevation of standards in teaching.]

The success of the better schools, the enthusiasm of the students trained in them, the opportunities which have opened up for these students after graduation, the scientific investigations leading to publication which have been carried on; all have contributed to spur other medical schools in different parts of the country to emulate the examples set.

There have been two main difficulties: (1) the financial one of equipping the expensive laboratories of anatomy, physiology and pathology and paying the staff sufficient amounts to permit them to devote their whole time and energies to the work; and (2) the absence of endowed hospitals under the control of medical schools or universities, into the wards, dispensaries, and laboratories of which students could be taken actually to participate in the routine work of diagnosis and treatment.

[Dr. Barker then describes the agencies which have been influential in securing the reforms, emphasizing especially the work of the Council on Medical Education and that of the Carnegie Foundation for the Advancement of Teaching recorded in the report of Mr. Abraham Flexner.]

The Council has performed its work almost wholly through the cultivation of medical opinion; it simply gives publicity to the information which it collects. It has no power whatever to dictate to medical schools or to set standards either for the schools or for the state examining boards, but it has so deliberately and successfully, through the currency given to the results of its inquiries, worked on the collective medical mind in the United States, that a moral pressure, irresistible in its coercive force, has come to be exerted. A school, for example, which is heralded in the over 50,000 copies of THE JOURNAL of the American Medical Association as one which turns out graduates of whom more than 20 per cent. fail at the state licensing examinations, or another, which, after personal and unbiased inspection by members of the Council, is classified as a "rejected" school, has a sealed fate.

The Council has been none the less successful for having avoided utopian attempts; it has been satisfied with a gradual, though steady, stride toward attainable ideals. It recognizes the manifold difficulties of the pedagogic situation, is aware of the necessity of taking time, of educating those concerned and, especially, of the indispensableness of endowment from the state, or from private funds if desired reforms are to be instituted. . . .

Through the various influences above mentioned inferior medical schools are rapidly being weeded out and the schools left are steadily being improved. The nation has set itself resolutely to the task of reconstruction and it will not rest satisfied until its medical schools have reached a degree of efficiency and attained to a power of public service which will bear favorable comparison with similar institutions anywhere in the world.

POSITION OF AND SOME TENDENCIES IN THE NON-CLINICAL DEPARTMENTS

On examination of the non-clinical departments of the better medical schools in the United States it will be seen that a definite policy has been established; the *principles of this policy must sooner or later be observed* by every medical school which hopes that its conduct may be held in good repute.

THE POLICY ESTABLISHED

The essentials of the policy include: (1) commodious laboratories equipped with all modern appliances for teaching and investigation in anatomy, physiology, pharmacology, biochemistry and pathology, (2) "full-time" professors with, for the more part, "full-time" assistants, trained or undergoing thorough training in these fundamental disciplines, men who are enthusiastic teachers and have a zest for, and success in, prosecuting original inquiries, and (3) an annual budget at the disposition of the staff adequate for improvement of equipments, for supplies and expenses and for the services of janitors, clerks and mechanical assistants. These departments are, therefore, not only places in which well-organized courses of instruction for medical students are offered; they are also centers in which knowledge is seethingly advanced.

Under this policy the non-clinical departments are flourishing. Glance through "American Men of Science" and make lists of those who have been led to cultivate these fields and have been notably successful in the work. You find an imposing array. Look over the journals, most recently founded, devoted to the different subjects and the proceedings of the scientific societies and you will be gratified to find how speedily and notably knowledge has been and is being increased.

The best American work is receiving adequate foreign recognition, and while but few European students have thus far been attracted to American non-clinical laboratories for work, the stream of students which formerly flowed in the other direction has to a large extent ceased.

DANGERS THREATENING THE NON-CLINICAL DEPARTMENTS

The non-clinical chairs in the medical schools may be to a certain extent, however, in danger. The possibility of evil has arisen not at all through hostile intention, but rather through certain conditions, partly external, partly internal, which may place them in a trying situation. Of these conditions I shall refer now only to three, viz., (1) the rise of institutions devoted solely to research, (2) the rapid formation of medical faculties in state universities, and (3) the pecuniary penalty attaching to chairs on a "university basis."

[In the full address these three conditions are discussed at some length. While the advantages of the institutes for research are emphasized, it is intimated that these institutions should be integral parts of universities and that the latter have made a serious mistake in losing the research institutes through failure to recognize the necessity of separate provision for the functions of teaching and research.

The author also explains why the demand for professors in the non-clinical departments has been greater than the adequate supply.]

. . . Thus, through the exit at the top of many of the best and through the entrance at the bottom of too many immature and partially trained, the high standards thus far maintained for the non-clinical chairs, run some risk of depreciation. At present, positions, such as they are, can be obtained too easily; the period of training is so shortened, as to make the attainment of a high grade of scholarship difficult. There is the dangererous possibility, too, of promoting to full professorships men of mediocre talent; who, in a longer and more exacting discipline, would find their academic level, or would actually be weeded out in a competition in which the prizes were larger and the number more extended of intellectually superior contestants.

[The financial status of the professor is next analyzed and the insufficiency of existing salaries pointed out.]

The occupants of non-clinical chairs, like those of the chairs in the arts departments, have little means of supplementing their salaries by outside work. Some of them do executive work which yields small additional emoluments; some write text-books which, if successful, bring in a modest amount of royalties; now and then a professor receives extra pay as a member of a federal, state or municipal commission of experts. There is no income, or very little, from consultation practice, for anatomists, physiologists and pathologists have but rarely had the clinical training necessary to make them expert diagnosticians and therapeutists; moreover a code of ethics has gradually developed which goes far to prevent such professors from engaging in the practice of medicine, except possibly a limited consultation work, even when their experience has been such as to make them equal to it. The feeling prevails that such outside work, so different from that of his regular activities, lessens a professor's opportunities for scholarly study by its encroachment on his time and energies and detracts from the dignity, simplicity and high-mindedness of the teacher's calling. . . .

That some great teachers and investigators are attracted to the non-clinical chairs despite the small material rewards and the heavy financial and social penalties pertaining to the positions, has been fully demonstrated; that some will continue so to be attracted we can be sure. Men who inordinately love gain and material advancement are not likely to work toward professorships; it is perhaps well that the professorial class is recruited elsewhere. The power of disinterested scientific creation and the passion for truth and research are seldom cerebrally compatible with the money-getting gift, the capacity to devote one's self to, and to keep the mind concentrated on, financial gain. The life of a professor is necessarily simple and frugal; his wife can make no pretense to the absurd and vulgar extravagance that Irving Batcheller facetiously and satirically describes as "keeping up with Lizzie." The career of a professor is often, however, one of profound influence and of steady happiness, of high honor and well-deserved respect, and these are rewards not likely to be regarded lightly among the more idealistic of our youth.

Still, it must frankly and anxiously be admitted that there are elements in the financial status of non-clinical professors which make us stand in pause when we think intently on the situation. No matter how keen the love of teaching, how hearty the satisfaction in solving scientific problems, a strong man can scarcely be expected to devote himself to a life of instruction and research when the remuneration is inadequate to the real needs of himself and his family during his period of activity, and to provision for his old age.

It is highly desirable that the compensation of professors should be a little above rather than below the line of comfort for the locality in which they live. It should be large enough to furnish the necessaries and conveniences of life, without superfluity, and should not be so small as to prevent a man from saving each year a part of his receipts, even though a smaller fraction of them than Bacon recommends. The struggle to live, financial worries, inability to educate the children of the family, too great personal hardship, and the social penalties of too small an income are sure more or less to inhibit a man in his work. . . .

Society ought not financially so to penalize the professorial class that the occupancy of chairs by the stronger personalities will be limited to bachelors, to childless men, to men enriched through the accidents of inheritance or marriage, or to married men who consent to doom their wives and children to the mitigated happiness which poverty affords.

Men of some sort there will naturally be who will seek salaried positions, no matter how low the salary, and, fortunately, the love of teaching, of study, and investigation will always secure a certain number of gifted men whose passion will make them work at the thing they like under any conditions. But if the fiscal arrangements of professorships were to be made in such a way that they attracted chiefly mediocre persons to whom a salaried position spells security, the higher interests of scholarship would suffer. Attention need scarcely be directed to the progressive declension of our public schools through precisely this enforced withdrawal of their abler men.

The interest in, and joy of, work, the desire of public service, the anxiety to do something well, the longing for the good opinion of one's colleagues, the obtaining of leisure to devote one's self to the finer interests of life—these must always be the great motives which lead men to become university professors. The material rewards are not, however, wholly insignificant. They certainly exert some influence. . . . In salaried establishments, it is not always possible to avoid the defects of "institutionalism"—bureaucratic officialdom, the tyrannies of a mandarinate, and oligarchic indolence; those interested in the organization of asylums for the insane have repeatedly lamented this fact. .

[The author makes various suggestions for improving the financial status of professors.]

The education of public opinion to greater social recognition of the professorial class might help; it progresses rather slowly in a country in which "success' is largely, as yet, measured by income; those who have not learned how to get money and to keep it are too often, by the unthinking, indiscriminately classified, not quite, perhaps, as pariahs, cut off socially from hope, but still as futile persons, too innocent for "achievement" in a land of opportunities!

An especially pressing factor during recent years has been the gradual rise in the cost of living without any proportionate increase in the salaries of university professors. The average price of commodities has increased by 33 per cent. to 50 per cent., but the professor who was paid $2,000 or $5,000 before this rise took place is still compelled to live on the same amount. . . .

The whole situation should certainly be canvassed carefully and the means discovered for enhancing in various ways the social and pecuniary rewards of professors in the non-clinical branches of our medical schools.

POSITION OF AND TENDENCIES IN THE CLINICAL DEPARTMENTS

The policies followed in the clinical departments of the better university schools are far from uniform. There is, as yet, no unanimity of opinion as to the best way to improve these departments. All are agreed as to certain fundamental points: the desirability (1) of more thorough practical teaching and (2) of an increase in scientific productivity. How best to move toward the practical realization of these ideals is a question.

A STATE OF FLUX

The clinical departments of the medical schools of the United States are on the eve, it would seem, of important reforms. To bring them about, radical changes may be necessary. Faculties will, doubtless, be led to experiment in various ways; only after trials through a considerable period shall we be able to decide on the arrangements and organization suitable for general adoption in the better schools. A state of flux, already evident in the clinical departments, is, therefore, likely to continue and to become even more pronounced during the next decade.

In medicine, which is, and must always be, the department of primacy in a medical school, and also in surgery the tendency to fill chairs by attracting able men from a distance has finally begun. It was formerly impossible on account of the absence of school-controlled hospitals. The medical faculties were compelled to accept as their clinical professors men who, developing locally, were the physicians to municipal or to privately endowed hospitals. In no other way could "clinical material" for the instruction of students be obtained. Now that universities are beginning to have their own hospitals, or to enter into arrangements with other hospitals through which their professors are assured directing places on the hospital staff, professors may be called from a distance, or be selected from the local profession, on account of their skill in diagnosis and therapy, their ability as teachers and their power as original investigators.

THE PRINCIPAL CLINICAL CHAIRS AND THE SPECIALTIES

The three principal clinical chairs in a medical school must always be those of medicine, surgery and obstetrics. A general training in each of these branches is absolutely essential in the education of every medical student.

In the specialties, there is time, in the brief period of the clinical curriculum, to teach the student only the most salient methods of diagnosis and treatment, those suited to the needs of the general practitioner.

[The proper relation of the specialties to the principal clinics is somewhat fully discussed. The importance of adequate special clinics for the postgraduate work is emphasized.]

THE HOSPITALS OF THE MEDICAL SCHOOLS AND THEIR MANAGEMENT

The most pressing need in the clinical departments of the medical schools of the United States, at present, is that of school-controlled hospitals in which the students may actively participate in the work of diagnosis and treatment and, under skilled direction, be held responsible therefor. In the hospitals, the conditions should permit of an adequate organization for the three great functions of a university clinic—practice, teaching, and research. These hospitals should be large enough to supply sufficient clinical material in internal medicine, surgery, obstetrics and in the principal specialties. The organization should ensure a large degree of departmental autonomy while providing for proper correlation of the activities of all the clinics.

It is only here and there in the United States that one finds belonging to a medical school (1) a hospital of sufficient size, equipped with teaching and working quarters, with wards situated in immediate contact with commodious clinical laboratories, (2) an organization according to which the professors of the clinical departments of the medical faculty are also the principal physicians and surgeons on the hospital staff, the whole control of the individual departments being in the hands of the respective professors. Until medical faculties obtain by endowment or agreement facilities of this sort, the clinical sciences must remain backward in their development.

[In the complete text the hospital situation is analyzed, the difficulties now existing pointed out, and measures for improvement advised.]

DEPARTMENTS OF INTERNAL MEDICINE

The functions of each of the clinical departments are manifold and complex. Let me refer to some of the activities of the branch about which I know most; namely, internal medicine. If one attempt to resolve the functional complexity of that branch into its component aspects one can distinguish, at once, at least four principal parts:

1. The *practice of medicine* in the public and private wards and in the out-patient department and the laboratories thereto pertaining, by which I mean the actual diagnosis and treatment of disease in the patients who enter the clinic.

2. The teaching in the wards, in the dispensaries and in the laboratories of (a) undergraduate medical students; (b) assistants and associates; (c) physicians taking postgraduate courses in the department.

3. The prosecution, by professors, assistants and postgraduate students, of original inquiries in internal medicine, the search for new methods of diagnosing and treating disease, the attempt to advance our knowledge of the subject beyond its present boundaries.

4. The administrative duties, including the admission, transfer and discharge of patients, interviews and correspondence with physicians who bring patients, and with the relatives and friends of the sick, the relations of the clinic to housekeeping and nursing, the maintenance of records and statistics, the arrangements for publications, the superintendence of budgets and expenditures, the making of appointments and promotions, the attendance on departmental and inter-departmental conferences, the formulation of curricula, the organization, equipment and running of the several clinical laboratories, the library, and the museum, the integration of departmental activities, the development of an *esprit de corps*, etc.

THE PRACTICE OF MEDICINE IN THE CLINIC

Turning now to a little closer examination of the work of the medical clinic of a modern school and hospital it will be found that the practice of medicine in the clinic itself is, separately considered, no small task. In order that the teachers and investigators in the clinic may be sure of getting what they need, or prefer, in their work, a large number of cases from which to select must be admitted to the hospital. The larger the clinical material available the better. The time may come when, in addition to the general reception wards of the stationary clinic, there will be special wards to which may be transferred the cases most suitable for teaching, on the one hand, and for investigation on the other. The larger reservoir for the reception of the cases previous to selection will always be necessary, for in the first place, until a patient has been fairly well studied, one cannot be sure how valuable he may be for illustration in teaching or for the suggestion of problems for original scientific investigation; in the second place, every great hospital must, on humanitarian grounds, take in many cases which, at the time, may be of relatively little educational or scientific interest.

A large department for out-patients, a so-called "policlinic" or "ambulatorium," is also necessary for three reasons; first, on humanitarian grounds, to provide treatment for the poor who, though not well, are not so sick as to require admission to the wards of the hospital; again, as a feeder to the stationary clinic, to which can be sent the sicker patients, those exemplifying unusually well the pathological states under consideration at the time in the educational work in the wards, and those presenting obscure conditions, necessitating for diagnosis more elaborate studies than are feasible in the policlinic; and finally, for teaching purposes in the policlinic itself, for here material of a special kind becomes available for the teaching of students, including not only slightly ill patients suitable for the practical courses in physical diagnosis and other propedeutic studies, but also precisely the types of minor ailments which the young physician is most likely to meet when he starts out in practice.

[Dr. Barker describes in more detail the method by which the policlinic can be utilized for teaching, and also refers to the vexed problem of private wards in connection with university hospitals.]

The responsibilities of diagnosis and treatment of this vast collection of clinical material, public and private, stationary and ambulatory, are a grave burden which the clinical staff must bear. The mere technical procedures of the thorough examinations made and of the therapeutic measures carried out involve a large expenditure of time and energy. Students, house-officers, and senior assistants may well bear the brunt of this work, but, in addition, an associate professor, or in the larger institutions, preferably a full professor, may well devote the major part of his time and energies to it, leaving most of the teaching and experimental investigation to others. The philanthropic work of the hospital, as well as the reputation of the institution among physicians and among the laity, depends on the thoroughness and courtesy with which this work is done. Moreover, the teaching and investigative functions of the clinic can be properly developed by those who are devoted especially to them only after this fundamental function of diagnosis and treatment has been fully provided for.

[Here the author calls attention to the great differences in the functions of men who work in clinics and those who work wholly in laboratories.]

The application of the principles of "scientific management" to the details of the work in the clinic promises improvements. If every element in the work of the clinic, from out-patient department to private ward, were subjected to searching inquiry, much waste of time, waste of energy and waste of material could be eliminated. At present there is little uniformity in the technic of clinical examinations and the personal element enters far too greatly. It is highly desirable that experts shall decide on the one best method to use in each instance, that these best methods shall be adopted as standards, the efficiency of all the workers being gradually brought up to these standards by careful instruction, and the organization made such that the plans will be self-perpetuating. This task is far easier to talk about than to accomplish, but it should be undertaken.[1] Modern commerce is developing systems of efficiency beside which the management of clinics cuts a sorry figure. We need a "commercialization of medicine" in the good sense and must see to it that the term "medicalization of business" is not coined as a byword of reproach!

THE TEACHING OF INTERNAL MEDICINE

In the performance of the second great function of a medical clinic, that of teaching in the wards, in the dispensaries and in the clinical laboratories, a fairly large staff, a well-thought-out plan and the devotion of much time and energy are essential. The amount of teaching in a department of internal medicine is, and should be, greater than in any other department of a medical school. It makes up a large proportion of all the work of the third and fourth years, and from now on is likely to include also a part of that of the second year of the undergraduate course.

Since the graded medical course was inaugurated by Northwestern University many years ago, American clinicians have gradually arranged a sequence of studies in the medical clinic which permits of a methodical advance in the instruction. The student from the beginning of his clinical studies is made regularly and purposefully to climb a ladder which connects the fundamental training of the non-clinical departments with the professional occupation which he is to take up after graduation. Instead of the didactic and merely demonstrative teaching which formerly prevailed, a thorough practical training in clinical work is now required. After a general introduction to clinical methods and aims at the end of his second year, the student is, in his third year, instructed in the principles and art of physical diagnosis (inspection, palpation, percussion and auscultation), and he is taught, in the systematic practical course given in the clinical laboratory, how to make examinations of the sputum, urine, stomach contents, feces, blood and the various body fluids. In the third year, too, he learns the method of taking clinical histories and of keeping protocols, hears a certain number of general didactic lectures, attends amphitheater clinics which stimulate his interest, studies a good text-book, and is tested as to his progress by carefully conducted recitations. In the latter part of the third year he may profitably engage in the actual history-taking, physical examination and therapy of ambulatory patients in the policlinic.

Important as this propedeutic work is, it is overshadowed in benefits conferred by the medical work of the fourth year, when the undergraduate student is required actually to do an important part of the work in the stationary clinic. Here, as a clinical clerk, he has a certain number of beds assigned to him and is permitted to regard the patients occupying them as his patients, for whose study and care he is personally, in large degree, responsible.

[In the following section, which is here omitted for lack of space, the importance of teaching by the method of clinical-clerkships, introduced into this country by Dr. Osler, is entered on.]

Students and staff thus work together in the medical clinic as a harmonious group. The cases under examination are compared with similar cases in the literature. The spirit of thorough investigation is cultivated; each worker is encouraged to ask himself how the particular cases immediately in his care can be more completely analyzed and what problems they present suggestive of experimental or statistical inquiry. The treatment insticertain fundamental points: the desirability (1) of more thorough practical teaching and (2) of an increase in scientific productivity. How best to move toward the practical realization of these ideals is a question.

At present there is little uniformity in the technic of clinical examinations and the personal element enters far too greatly. It is highly desirable that experts shall decide on the one best method to use in each instance, that these best methods shall be adopted as standards, the efficiency of all the workers being gradually brought up to these standards by careful instruction, and the organization made such that the plans will be self-perpetuating. This task is far easier to talk about than to accomplish, but it should be undertaken.[1] Modern commerce is developing systems of efficiency beside which the management of clinics cuts a sorry figure. We need a "commercialization of medicine" in the good sense and must see to it that the term "medicalization of business" is not coined as a byword of reproach!

THE TEACHING OF INTERNAL MEDICINE

In the performance of the second great function of a medical clinic, that of teaching in the wards, in the dispensaries and in the clinical laboratories, a fairly large staff, a well-thought-out plan and the devotion of much time and energy are essential. The amount of teaching in a department of internal medicine is, and should be, greater than in any other department of a medical school. It makes up a large proportion of all the work of the third and fourth years, and from now on is likely to include also a part of that of the second year of the undergraduate course.

Since the graded medical course was inaugurated by Northwestern University many years ago, American clinicians have gradually arranged a sequence of studies in the medical clinic which permits of a methodical advance in the instruction. The student from the beginning of his clinical studies is made regularly and purposefully to climb a ladder which connects the fundamental training of the non-clinical departments with the professional occupation which he is to take up after graduation. Instead of the didactic and merely demonstrative teaching which formerly prevailed, a thorough practical training in clinical work is now required. After a general introduction to clinical methods and aims at the end of his second year, the student is, in his third year, instructed in the principles and art of physical diagnosis (inspection, palpation, percussion and auscultation), and he is taught, in the systematic practical course given in the clinical laboratory, how to make examinations of the sputum, urine, stomach contents, feces, blood and the various body fluids. In the third year, too, he learns the method of taking clinical histories and of keeping protocols, hears a certain number of general didactic lectures, attends amphitheater clinics which stimulate his interest, studies a good text-book, and is tested as to his progress by carefully conducted recitations. In the latter part of the third year he may profitably engage in the actual history-taking, physical examination and therapy of ambulatory patients in the policlinic.

Important as this propedeutic work is, it is overshadowed in benefits conferred by the medical work of the fourth year, when the undergraduate student is required actually to do an important part of the work in the stationary clinic. Here, as a clinical clerk, he has a certain number of beds assigned to him and is permitted to regard the patients occupying them as his patients, for whose study and care he is personally, in large degree, responsible.

[In the following section, which is here omitted for lack of space, the importance of teaching by the method of clinical-clerkships, introduced into this country by Dr. Osler, is entered on.]

Students and staff thus work together in the medical clinic as a harmonious group. The cases under examination are compared with similar cases in the literature. The spirit of thorough investigation is cultivated; each worker is encouraged to ask himself how the particular cases immediately in his care can be more completely analyzed and what problems they present suggestive of experimental or statistical inquiry. The treatment instituted can be carefully observed, for the work is concentrated, the students practically living in the medical wards for several months at a time; any results attributable to therapy can be observed and recorded. If a patient gets well the students are urged to follow up his subsequent history; if he dies they attend the autopsy in the pathologic laboratory and compare the anatomic findings with the clinical inferences which have been drawn during life.

---

[1] Taylor, F. W.: Scientific Management, N. Y. 1911; Gantt, H. L.: System, February, 1911; Cooke, M. L.: Bulletin of Carnegie Foundation, 1910.

In all this medical work, in both the third and the fourth years, it is essential that the students be divided into small groups and that each group be directly supervised by some member of the clinical staff. The immediate hourly supervision will, of necessity, devolve on the younger men on the staff, but a heavy burden also falls on the senior members of the department who must, themselves, keep in intimate touch with the students and junior staff—controlling, criticizing, reviewing, suggesting, encouraging. At least one full professor and two associate professors, whose function shall be predominantly teaching, are needed to plan and to conduct this work; in larger clinics it would be of advantage to have two full professors assigned to this function. In some of the schools, the teaching professors will also be the authors and revisers of text-books of medical practice.

[Continuing the description of the teaching in the clinic, the article deals with (1) the instruction given to the junior men on the staff, and (2) postgraduate courses in internal medicine.]

DISCOVERY IN INTERNAL MEDICINE

The third great function of the clinic of internal medicine is that of original investigation. It is a fortunate feature of clinical work, one doubtless that has had much to do with that steady progress in knowledge which throughout time the clinics have made, that even the routine work in a clinic is largely work of research. Each new patient is a problem for investigation; the clinician applies the methods he has learned and tries to solve it. The essentially inquisitive nature of the everyday work of the clinician has to be personally known to be fully appreciated. In addition to the ordinary routine of clinical work, physicians are constantly trying out new methods of examination and treatment that have been devised and recommended; this work, carefully done, the observation being accurately recorded and analyzed, affords material for statistical inquiry, the results of which are often of high importance to the profession. When a new method of determining clinically the size of the heart has been proposed, or an early diagnostic test for typhoid fever or for syphilis or for carcinoma of the stomach suggested, long experiential proving in the clinics must decide as to its value before it is accepted for general routine. A great clinic, scientifically controlled, can thus continually advance knowledge and help on the practical work of the profession.

It is, naturally, not the function of the clinic to do work in abstract anatomy, physiology or pathology. The aim and purpose of the clinic is on the contrary to continue the applications already made, and to make new applications, of the facts of anatomy, physiology, pathology, chemistry, etc., to the solution of problems in diagnosis and therapy suggested by patients who come to the clinic for help. Unless clinical men fully realize this point, unless they have a full consciousness of precisely what the clinic is for, they may be led astray by those who feel that "applied science" is very different from "science."[2] Clinicians are sure, now and again, to make certain contributions to pure physiology or pathology when trying to solve their own problems in diagnosis and therapy. They will be glad when their work so contributes, but this should not be the main aim and purpose of that work; as soon as a man in the clinic finds it to be so, it is time that he left the clinic and transplanted himself to a laboratory of physiology or pathology. Clinicians must jealously guard opinion in this matter; otherwise their sciences cannot progress.

[A section omitted here emphasizes the significance of an atmosphere of original research for students and staff.]

In the United States, the emphasis has been laid rather on the teaching of students; clinical research has been, until recently, less cultivated. This may explain the higher state of clinical science in Germany, on the one hand, and the better physicians trained by the good schools in the United States on the other. Germany ought to reorganize its clinical teaching so as to make better doctors[3]; in the United States we should set about increasing the scientific productivity of the clinics. . . .

In order that clinical research may make more rapid advance, and the sciences of diagnosis and therapy be furthered, the experimental method should be more extensively employed. Owing to the peculiar conditions which have prevailed in the clinics up to now, only a few men, either in Germany or the United States, have had the time, interest, training and independent income which have permitted them to do extensive original work by experimental methods in laboratories directly attached to the clinics. Recently, however, more of this work has been done. It has been very welcome, and the time has come when it would seem desirable to make this kind of research more systematic and purposeful, less casual and accidental.

[Dr. Barker lays stress on the establishment, in addition to teaching and diagnostic laboratories of several special research laboratories in the medical clinic (biochemical, serologic, physiologic and psychopathologic), directed by well-paid scientific men.]

It would be short-sighted of internal medicine to neglect these powerful engines of exploration and enrichment. The other departments of applied science have set us the example. Technology has demonstrated the efficacy of paid research work for the promotion of the industrial arts (metallurgy, brewing, electrical engineering, sugar refining, food preservation, the manufacture of arms and ammunition, etc.). It would be a distinct advantage if at least one liberally endowed full professorship were provided in the clinic of internal medicine, in which a man of original ideas, thoroughly trained in methods of research, could, undistracted by administrative work, by private or hospital practice, or by undergraduate teaching, devote his whole time and energies to it. A mind full of heuristic hypotheses, a curiosity which compels the accurate testing of them, a body inured to intense and confining work, the privilege of continuous, uninterrupted application to laboratory studies, a guarantee of financial independence, liberal support in the form of equipment, facilities for experimentation, assistants and mechanical aids, and the entire sympathy and cooperation of those who attend to the major part of the practice and the teaching of undergraduates in the clinic would be necessary to make the venture fruitful. Assume the existence of such conditions in our departments of internal medicine, and find for the research professorships men of the type of Louis Pasteur, Robert Koch, Paul Ehrlich, or Simon Flexner—what dare we not expect in the way of extension of diagnostic recognitions and of means of cure?

---

[2] A mathematician sometimes feels that his work is more scientific than the work of the chemist or physicist; the latter, in turn, is too prone to regard the biologist or physiologist as an unfortunate worker in applied science, and to speak with some contempt of the efforts with complex and mixed substances made by the biologic chemist, or the immunologist; the physiologist and the pathologist again only too often fail to attribute scientific value to the efforts at application of the facts of their subjects made by clinicians. There will always be, I fear, this misunderstanding of the applied sciences by the sciences basal to them.

[3] An effort in this direction, recently made in Germany, may be seen in the "hospital year" now required at the end of the medical course there. It appears to correspond to our hospital internship, made compulsory.

And what an opportunity such an arrangement would offer for postgraduate study! A few advanced scholars, desiring to widen the science of internal medicine, could cooperate with such a research-professor in the "master work-shop," and, according to their ability, experience the wonderful joy of creative work. One who has once been permitted so to participate will never forget it. Many regard this last and highest phase of personal education as the acme of their inner experience.[4]

Despite the unfavorable conditions now existing in the clinical departments, strong men have been attracted to them. All things considered, patients are being very well cared for, good physicians are being trained, a very fair amount of original work has been produced. The bibliographic output, including text-books, handbooks and publications of original research, compares favorably with that of any one of the laboratory subjects. As to foreign recognition, it has been fully as great for the clinical chairs, if not greater, than for the non-clinical departments. Many foreign clinicians have visited American clinics and most of the foreign students who have come to this country to work have entered clinical rather than non-clinical departments. Several clinical text-books have been and are being translated into other languages.

THE MOVEMENTS TOWARD REFORM

The tedium of this long description of the functions of a medical clinic would scarcely be justifiable were it not for my desire clearly to establish a fact of importance, namely, the growth of the functions of the clinic to a size and complexity no longer compatible with the form of its present organization.

Hitherto there has been only one professor at the head of a clinical branch, and he has been supposed to engage in, care for and control all these varying activities and, in addition, to make the major part of his income in practice outside the hospital, only a few institutions, thus far, having been able to pay salaries which would defray even a portion of the cost of the clinician's living. Surely the superhuman has been expected!

We have now briefly to consider how the clinics can best be organized to meet modern requirements, and I shall again refer chiefly to the medical clinic, assuming that a plan which will suit its exigencies may, with certain modifications, be applicable to the other clinics.

[Methods of reorganization and reform, based on a functional division of labor, are next suggested.]

Those who devote themselves chiefly to the care of patients in the clinic need not be men who do a great deal of teaching and investigation. Those who are mainly responsible for the teaching in the undergraduate school should not be burdened with the care of too many patients and would of necessity have to limit the time given to investigation. Those, in turn, who give their time and energies almost wholly to research should be protected, as far as possible, from the teaching of undergraduate medicine and from the care of practice and administration.

Here, then, we have in mind a clean-cut conception of an ideal of organization toward which we may strive. What is now a single professorship could be replaced by a cooperative committee of professors in charge of a large and differential staff.

[The section omitted here deals with the "headship" of the department and the cooperation of the staff.]

In an address delivered some years ago, entitled "Medicine and the Universities,"[5] I made some suggestions regarding the clinical branches; even then, though I was engaged entirely in laboratory work, it seemed to me that the clinics were under-manned and that the work in them was insufficiently differentiated. In that address it was intimated that the time might come when, in the clinical branches, we should have at least two kinds of professors: (1) Professors on a so-called "university basis," paid salaries large enough to enable them to devote their whole time and energy to teaching or investigation, without engaging in private practice; and (2) professors who give a part of their time to the care of patients in the hospital, to teaching or to investigation, and who, though paid smaller salaries, obtain their income chiefly from the fees of private patients, preferably from consultative or operative work. The ideas there set forth, in the main, still hold good, though it is doubtful if they can be applied in precisely the manner I then suggested. Though the clinic then seemed complex, I know, to-day, even more of its intricacies and difficulties, and the problem looks less simple in solution at close range than it did at a distance.

Were a new medical school to be started, with liberal endowment, it would be an interesting experiment to try an organization in which a functional division of labor, such as I have outlined, is provided for and in which some of the professors, especially those devoting themselves almost entirely to research, will be paid sufficient salaries to permit them to escape from practice.

It has hitherto been taken for granted that the professor of medicine in the medical school will engage in medical practice and that the professor of surgery will have his private patients, each reaping the financial rewards attending on such work. The prominence of such men and their unusual training and opportunities have made them, as a rule, much-sought consultants rather than general practitioners, though many of them naturally began with general private practice in their respective branches, and, as their work grew, limited it, later, to consultative or operative practice. Only rarely have the occupants of clinical chairs been paid living salaries.

[An omitted paragraph comments on the public demands made on clinical professors and the question of the substitution of salaried public medical service for private enterprise.]

In our reorganized medical schools it does not seem to me probable that it will be desirable soon, if ever, to have all the men of the faculty composed of non-practitioners. It would seem distinctly advantageous to have at least some of the teachers of undergraduates and some of the men who care for the patients in the hospital also engaged in private practice, at least in consultative or in operative work.

---

[4] Cf. Ostwald, W.: Die Umschau, January, 1911.

[5] American Medicine, Phila., 1904.

In all attempts at reconstruction our efforts should, at first, be tentative. It would be a mistake to start with any cut-and-finished garment that we should ask the medical schools immediately to don. Though having the essentials of our ideals in mind, the proper method of attaining to them and the proper expedients would have to be slowly established. At an early stage of reform, anything like extreme measures should be sedulously avoided. In making profound changes the process of transition must not be flatly ignored. The ideal clinic can scarcely be attained by proclamation. The obstacles in the way of progress must be carefully measured and we must keep in mind the cardinal fact that "all true development and progress are out of and because of what has gone before."

It is among the inconveniences attending all important reforms that the disciple overstates the teacher, exaggerates some features of his doctrine and is oblivious to, or insufficiently appreciative of, others. There is always danger of confusing novelty with originality and alteration with progress. Because we desire research is no reason for doing away with teaching and practice in the clinic. Nor would, in my opinion, the limitation of every professor in a university to the material rewards of an insufficiently salaried position prove a panacea or a magic "open sesame" to the medical millennium.

Some enthusiasts urge the summary dismissal of the clinical professors now active and the substitution of non-practicing men. Even if this were advantageous for all the chairs, as some erroneously think, it would be difficult to apply such an organization abruptly in the schools already established. Men who now occupy the clinical chairs and who have of necessity ordered their lives for the double function of professorships, on the one hand, and of consultative or operative work, on the other, have become so involved in obligations that they could not suddenly change to a salaried basis without great hardship to themselves and their families, and loud complaints from the public.

[The cost of living of the clinical professor is the topic of an omitted section.]

Hitherto there have been no endowed clinical professorships and should they be established, men would have to be trained especially for them. For this reason alone, the change could not be promptly brought about; and besides, any extreme and harsh measure like compulsory expropriation of the chairs might do damage inasmuch as anything that makes the tenure of university professorships insecure injures the universities.

It must be kept definitely in mind that the majority of the present incumbents of clinical chairs hold them in good faith; that they do their best in the conditions that now exist; that they, as much as any group, desire to see the clinical subjects advanced, to have the patients better cared for, to improve the teaching, and to augment the scientific output. The rightfulness of the kind of work the clinical men are doing has always been taken for granted. It may be a mistake for our medical schools to continue to have all clinical professorships as they have been; it may become educationally advantageous radically to alter the vast tradition of relationships in which clinical teachers now live. If so, the change can doubtless be brought about in an orderly and reasonable manner, and no ingratitude should be shown to those who up to now have tried to hold the torch aloft under unfavorable conditions. Above all, all honest, earnest, hard-working men should be protected from the zeal and overstatements of headlong advocates who insinuate the absence of ideals among clinical men, or talk of graft, rascality, commercialism and the exploitation of the clinical chairs for private profit.

The reconstruction in the clinical departments, when it is undertaken, ought, therefore, to be a sane and gradual process, a process of careful readjustment to changing conditions, going only as fast as men can be suitably trained and academic opinion correspondingly educated. Carried on in such a way, the reforms will be welcomed and hastened by every progressive, right-thinking clinician. Our better physicians and surgeons are broad-minded men; they are by no means devoid of the quality of self-abnegation nor of the spirit of public service; on the contrary, they are entirely capable of assuming their fair share of renunciations when conditions demand them, and of making personal sacrifices for the general good. Convince such men of the evil which exists and they will be no antagonists to the forces of reform, but, on the contrary, willing leaders of those who try to root the evil out.

After provision has been made for school-controlled hospitals, in which students may live and work, we must find places for the different kinds of clinical men —practitioners, teachers, investigators. There is room for all three types, and all three kinds of work are desirable and honorable. We have a homely saw to the effect that square pegs should not be put into round holes, an adage which finds its more polished equivalent in the Greek "Character is Fate." In every branch in a medical school students should come into contact with the stimulating investigator who is ever pushing forward the boundaries of knowledge; he should learn the main facts that have already been discovered from a teacher who knows how to collect them and to transmit them to others, and he should have the opportunity of watching the example of practitioners who come into contact with all sorts of patients and all sorts of doctors, who are acquainted with the great variety of clinical puzzles which are presented to the consultant for solution and who learn the virtues and defects of the men now engaged in medical practice in different parts of the country.

After giving these matters much consideration, there is one suggestion that I should like to offer as an immediate means of magnifying the scientific productivity of our clinics and of training men for leadership in them. Provide endowment for the maintenance, in each clinic, of a group of young scientists of proved ability and capacity for development, and relieve these men of most of the routine work of teaching and the care of patients, that they may have leisure for investigative work in the wards and clinical laboratories. A suggested scale of remuneration for such men might be an initial salary of $800 or $1,000 per year and living in the hospital, with a yearly increase of $200 or more for the next ten years. These men, so kept at work during their most productive years—usually between the ages of 25 and 45—would rapidly increase the scientific output of the clinics, and would speedily form a group of scientific men in the clinical branches from among whom, later on, professors in medical schools and investigators in research institutes could satisfactorily be chosen. Appointed to professorships, men so selected would not need to be hedged about by too great restrictions; their training in scientific methods and ideals would have been such that they could not quickly be spoiled. There should then be no attempt to interfere with the full play of their individualities; their positions should be made as unhampered as possible; they would of themselves chip away "the spendthrift liberties that waste liberty," and devotedly give their time and energies to the advancement of the subjects they represented. Their appointments as professors might automatically cease at the end of a given term of years, or when a certain age limit had been reached.

This occasion does not, of course, permit of any full discussion of the points I have raised. Perhaps I have said enough to call some of the interests to mind and to assure you that the men connected with the medical schools in the United States, like those in Canada, are doing all they can to elevate standards and to improve conditions in that noblest of all professions—medicine.

ANATOMIC CONDITIONS BEARING ON THE RELATION BETWEEN DISEASES OF THE EYE AND DISEASES OF ACCESSORY SINUSES *

WILLIAM E. SAUER, M.D.
ST. LOUIS

The eye and the nasal accessory sinuses are intimately related; in fact, the bony walls of the orbit are formed chiefly by the walls of the sinuses. The upper wall is formed largely by the floor of the frontal sinus, while the inner wall is formed principally by the lateral wall of the ethmoid cells, and the floor of the orbit by the roof of the maxillary sinus.

The bony walls are very thin, varying from 1 to 12 mm. in thickness. Aside from being at times of tissue-paper thinness, they may be defective; that is, they may have dehiscences. These dehiscences allow the mucous membrane of the sinuses to come in direct contact with the orbital tissues or the optic nerve. The dehiscences may be due to senile atrophy or to formative anomalies. Zuckerkandel reports fourteen and Onodi eighteen cases of congenital dehiscences of the paper plate of the ethmoid. These openings varied from 4 to 28 mm. in the sagittal and from 4 to 8 mm. in the vertical diameter. Merlin reports one case in which a dehiscence of the paper plate of the ethmoid connected the ethmoid cells with the orbit, frontal, and sphenoid sinuses. Onodi also observed three cases in which the frontal sinus communicated directly with the ethmoid cells and orbital cavity. Zuckerkandel reports four cases in which dehiscences of the sphenoid sinuses were connected by congenital dehiscences of the lateral wall of the ethmoid sinus; all four cases showed dehiscences of the orbital wall of the sphenoid.

In addition to those already mentioned, dehiscences of the frontal sinus occur frequently in the form of small openings, which are in part circular and part lineal. These little openings, Helly designates as "venenlocher." Kuhnt has shown that two of these small vessel openings, one of which is just at the inner orbital angle, and the other just behind the incisura orbitalis, are the usual routes for the passage of infectious material from the frontal sinus to the orbital cavity; another point of predilection in cases in which the frontal sinuses are large is at the junction of the middle and lateral portion of the orbital plate of the frontal. Onodi lays special stress on a defect which occurs in the ethmoid canal. The canal extends from the anterior ethmoidal foramen on the wall of an orbital cell or frontal sinus, to the anterior cerebral fossa. In this canal lie the anterior ethmoidal artery vein and nerve. He has shown that this canal at times consists only of a groove or semi-canal, with its vessels and nerves covered only by the mucous membrane of the sinus or orbital cell, bringing the mucous membrane in direct contact with the orbital tissues at one end and the dura mater at the other. Since a diseased process in the frontal sinus can easily extend by direct continuity of tissue to the orbit or dura, the importance of this canal at once becomes apparent.

Merlin and Zuckerkandel also report having observed dehiscences in the inferior orbital wall, thus bringing the periorbita and periosteum of the maxillary sinus in direct contact. The dehiscences in the paper plate of the ethmoid explain the occurrence of orbital emphysema, which results from sneezing or violently "blowing the nose" in otherwise normal individuals.

If these dehiscences are present when there is an existing suppuration, very little resistance is offered in preventing an extension into the orbit, as the periosteum of the sinus walls, as well as that of the orbital cavity, is not only very thin, but very poorly nourished.

The relation of the venous circulation of the sinuses to that of the orbit is most important. The anterior facial vein has its origin in the angular vein and anastomosis with the nasofrontal vein. The superior ophthalmic vein, commencing anteriorly in this nasofrontal vein, enters the orbit and passes outward above the optic nerve through the orbital fissure into the cavernous sinus. During its course through the orbit it receives, according to Birsch-Hirschfeld: (1) a vein from the lacrimal gland, (2) a vein from the frontal sinus, (3) a vein from the antrum of Highmore, (4) a communication from the inferior ophthalmic, (5) a communicating vein with the vein that anastomosis the angular with the cavernous sinus, (6) anterior and posterior ethmoidal veins, (7) muscle veins, (8) lacrimal vein, (9) central vein of the retina.

Through the ethmoidal veins and the nasofrontal vein, and the above mentioned branches of the superior ophthalmic, which communicate with the veins of the frontal and maxillary sinus, a thrombophlebitis may readily extend from the sinuses to the orbit or dura. Kuhnt reports three cases of embolism of the central vein of the retina from maxillary sinus empyema. According to Onodi, the venous plexus of the maxillary sinus bears a relation to a branch which bores its way through the sphenoid sinus wall. The veins of the sphenoid sinus may stand in direct relation to the ophthalmic plexus and cavernous sinus.

The arterial connection between the orbit and the sinuses is of much less importance. The posterior ethmoid is a branch of the ophthalmic and ramifies in the ethmoid cells. The anterior ethmoidal, also a branch, in its passage through the ethmoidal canal or semi canal, as before mentioned, may in connection with its vein, be of considerable importance as a route of infection from the frontal sinus to the orbit.

There seems to be very little exact knowledge regarding the lymphatics of the orbit. The presence of lymphatic vessels in the orbit is questioned by some. Birsch-Hirschfeld was able to demonstrate the presence of lymphatic spaces with well defined endothelial linings, in the adipose tissue, between the muscles, in the lacrimal gland, in the region of the optic nerve and in the periosteum. The larger spaces were in the neighborhood of

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

the larger vessels. He was, however, unable to demonstrate the direction of the lymph flow. Regarding the relation of the lymphatics of the orbit to the lymphatics of the nose, Birsch-Hirschfeld quotes Herman, who states that the lymphatics of the nose, with those of the face and the nasolacrimal duct, are in communication with those of the orbit. The post-mortem findings in the cases reported by Pagenstecker and Hajek, in which meningitis resulted from frontal and ethmoidal suppurations, no bone involvement was found, from which these authors concluded that the infection may have traveled by way of the lymphatics. It, therefore, seems probable that the orbit could likewise become infected through the lymphatic channels in connection with diseases of the nose and accessory sinuses.

The sphenoid cavity does not, as a rule, come in relation with the orbit, but its thin and often defective walls may be in relation above with the optic chiasm, sinus intercavernosi, the optic nerves, and laterally on each side with the cavernous sinuses, the communicating vein between the superior and inferior ophthalmic veins, and at times the central vein of the retina.

The proximity of the optic nerve to the sphenoid sinus and posterior ethmoid cells has been carefully worked out by a number of authors, viz., Berger, Tyrman, Hajek, Killian, Avellis, Onodi, Loeb and others. Their anatomic studies have shown that there are a great many variations in the relation between the sphenoid, the posterior ethmoid cells, orbit and optic nerve. Onodi was the first to show that the last posterior ethmoid cell is at times in relation to the optic nerve. Up to that time the contiguity to the sphenoid sinus alone was mentioned. Berger and Tyrman first called attention to the fact that the sphenoid sinus is not always in relation to the optic nerve. The bone between the sinus and the nerve may reach a thickness of 12 mm. This explains why in an extensive disease of the sinus, the nerve may not be involved. In Onodi's studies of the various relations existing between the sphenoid and posterior ethmoid and the optic nerve, he found, among others, the following of importance: the left posterior ethmoid cell may constitute the medial wall of the right optic canal. The right posterior ethmoid may constitute the inferior wall of the optic canal on both sides, and the wall of the entire optic sulcus. The left sphenoid sinus may constitute the inferior wall of the right optic canal. The right sphenoid sinus may border medially only on the left optic nerve. The left sphenoid sinus may constitute the inferior wall of the right optic canal and the wall of the right third and middle third of the optic sulcus. The left sphenoid sinus may constitute the inferior and medial wall of the optic canal on both sides and the wall of the entire optic sulcus. The left sphenoid sinus may also constitute the inferior and medial wall of the left optic canal and the inferior wall of the right optic canal, also the wall of the entire optic sulcus.

Onodi has further shown that when the posterior ethmoid cell is in relation with the optic nerve, the bony wall between them is usually very thin. He also illustrates two cases in his atlas which are highly instructive. In one the optic canal comes through a posterior ethmoid cell for a distance of 12 mm. In the other, the optic canal lies free in the sphenoid for a distance of 10 mm. The intimate relation of the optic nerve and the ethmoid and sphenoid sinuses not only shows the great liability to blindness in diseased conditions of these cavities, but also the danger of wounding the nerve in operative procedures in these cavities. Loeb lays stress on the position of the opening of the sphenoid cavity. He points out that the higher the opening of the sphenoid, the closer the stagnant pus comes in contact with the nerve, therefore the increased likelihood of nerve involvement. He has shown that in some instances the opening of the sphenoid cavity is on a level with, or even above the optic nerve.

The anterior ethmoid cells are not, as a rule, in relation to the optic nerve, but may be when they are large enough to replace a posterior ethmoid cell.

The frontal sinus may be in relation with the optic nerve, in those cases where the cavity representing the ethmoid merges with the frontal and the wall of their common cavity constitutes the medial wall of the optic canal, as occurred in a case described by Onodi.

These various relations which the optic nerve may bear to the nasal accessory sinuses explains the occurrence of involvement of the nerve on both sides in diseases of the sinus on one side, or even involvement of the nerve on the opposite side.

The fifth cranial nerve in its passage along the outer wall of the sphenoid sinus may be involved in sphenoid disease. Thus Posey and Ellinger have reported corneal affections as a result of the fifth nerve involvement, due to sphenoid disease. The sixth nerve, in its passage through a groove in the sphenoid, is often separated from the sphenoid sinus by a very thin wall. This nerve supplies the external rectus. A paralysis of the muscle is frequently concomitant with an acute rhinitis. Holmes maintains that the paresis cannot be explained, except as a result of disease of the sphenoid.

EYE COMPLICATIONS ARISING FROM DISEASES OF THE NASAL ACCESSORY SINUSES *

ALBERT H. ANDREWS, M.D.
CHICAGO

In presenting the subject of eye complications resulting from diseases of the nasal accessory cavities, there is much that has been said so often that it seems unnecessary to repeat it. It will be my purpose briefly to call attention to a few points which are generally recognized, and to emphasize certain obscure relations in the hope that we may be encouraged to make more careful observations and draw more accurate conclusions.

The relation between purulent accessory sinus disease and orbital cellulitis has long been recognized. As in mastoid disease we may have extensions from the mastoid through the bony walls by necrosis of bone, by the venous channels, by the lymphatics, and apparently by migration of the infection from one part to another contiguous part, so in purulent disease of the nasal cavities we may have extension to the orbit by any of the processes mentioned. Orbital cellulitis is characterized by pain, swelling, usually proptosis, redness and elevation of temperature. The symptoms vary according to the location and virulency of the infection. A cellulitis may subside without abscess formation, or an abscess may form near the orbital wall, and break into and drain through the accessory cavity from which the infection came. In the severer types there is severe pain, enormous swelling, chemosis of the conjunctiva, and sometimes cerebral symptoms such as headache, drowsiness, vomiting and disturbances of the pulse and respiration.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

The sight is impaired by displacement of the eye-ball and by stretching of the optic nerve. It may be lost entirely by involvement of the optic nerve. Detachment of the retina and panophthalmitis are occasional results.

The additional causes of orbital cellulitis, as given by Fuchs, are injuries, erysipelas, metastases in pyemia, typhus, scarlet fever, small-pox and purulent meningitis. Of all the causes, accessory sinus disease is undoubtedly the most common. The difficulty in getting at the cause of this trouble, as of many other lesions about the eye, is that those who see most of these cases are not able to correctly diagnose obscure nasal conditions. The diagnosis of orbital cellulitis is usually easy, but to determine whether of nasal origin or whether due to something else is sometimes difficult even for those accustomed to nose work. Transillumination of the frontal and maxillary sinuses, while not giving positive information, is of value. Inspection of the nasal chambers after shrinking the soft parts with cocain and some suprarenal product will frequently show discharge coming from or lying in the neighborhood of the ostia. The probe should be used, and in doubtful cases the diagnosis can be cleared up by direct exploration of the cavities.

TREATMENT

The subject of treatment naturally falls under four heads:

1. Preventive treatment by attention to pre-existing nasal conditions.
2. Nasal treatment during the attack.
3. Palliative treatment.
4. Surgical treatment.

The first two divisions—the preventive and the nasal treatment during the attack—apply to all diseases of the eye of nasal origin, but the discussion of them does not properly belong to this paper. The palliative treatment consists of anodynes when necessary, hot applications to the eye and general treatment such as is applicable to all acute inflammatory conditions. The detection of pus in the orbit is a positive indication for incision, but without fluctuation it is proper to make one or more deep incisions into the orbit whenever the swelling or the proptosis seems to have reached the danger-point. The pressure is thus relieved and the abscess can sometimes be found and drained when the external indications of pus are lacking. The position and direction of the eye-ball may help to locate the abscess. An abscess in the upper part crowds the globe forward and downward. Induration in the upper part of the orbit is likely to direct the eye downward, while an abscess, by pressure on the superior rectus muscle, may direct the eye upward. The same rule applies to abscess in other parts of the orbit.

Diseases of the lacrimal apparatus may result from extension of pathogenic microorganisms from the nasal cavity or from closure of the nasolacrimal duct by swelling of the soft tissue in the inferior meatus. The percentage of cases of lacrimal disease of nasal origin has been variously estimated, some believing that fully 50 per cent. are due to pathologic conditions in the nose. Others do not consider the nose as a possible etiologic factor. It is impossible to determine accurately the percentage since the patients are usually not seen until the conditions are well developed and then the pathology found about the nasal opening of the lacrimal duct may be the result rather than the cause of lacrimal disease. It seems sufficient for the purpose of this paper to say that in all cases of dacryocystitis, lacrimal abscess and epiphora, the nose, especially the accessory cavities, as a possible cause should be thoroughly investigated.

Diseases of the conjunctival sac and cornea of nasal origin may be due to invasion of microorganisms coming up through the lacrimal apparatus. Gradle believed the percentage of these cases to be very large. The reflex relationship existing between the conjunctiva and the nose can be easily demonstrated by irritating the tissues about the front end of the middle turbinate with a little cotton on an applicator. The conjunctiva becomes injected and in most cases lacrimation is increased. The same change is frequently seen after mechanical irritation of the accessory cavities although it is not so easy to demonstrate experimentally. In one of my patients, while the right sphenoid sinus was being explored, the conjunctiva of the right eye became congested, the redness, with some impairment of vision, lasting several days. It disappeared, however, without treatment, but occurred again several times after nasal manipulation. The etiologic relation existing between a conjunctival disturbance in a given case and disease of an accessory cavity is not easy to demonstrate positively. There is always the possibility of two or more simultaneous disturbances with different and independent causes, but from the way in which some of the conjunctival diseases clear up after treatment of an associated nasal accessory sinus disease the etiologic relation can be fairly assumed.

Muscular imbalance is believed by some to be very largely of nasal origin. Considering the thinness of the wall between the attachment of the rectus muscles and the sphenoid cavity and ethmoid cells, it does not require any great stretch of imagination to believe that disease of these cavities may impair the function of the muscles. The result of treatment of accessory sinus disease in the presence of muscular imbalance further goes to show that there is an intimate relation between the two conditions.

The muscular defect most commonly due to ethmoid disease is esophoria for distant vision with exophoria for close vision. The inflammation about the insertion of the internal rectus at the optic foramen seems to produce some contraction of the muscle thus drawing the eye nasalward from its normal position for distant vision, while the contractility is impaired, thus preventing the eye from turning inward sufficiently for normal, easy, binocular vision for close objects. It seems not improbable that the cases of headache caused by use of the eyes for close work, which have not been relieved by glasses and have been relieved by treatment of diseased ethmoid cells, are really cases of muscular asthenopia.

The pathologic relation between the accessory cavities and intra-ocular disease is not well understood. That such a relation exists is even doubted by some. The cases of iritis, choroiditis and retinitis associated with suppurative disease of the cavities are too frequent for the relation to be considered merely coincidental. I have seen some cases of recurring iritis giving a rheumatic history in which I found accessory sinus disease. It is a question not yet settled in my mind whether the iritis was of rheumatic origin or whether the iritis and the rheumatism may not have both been due to infection from the nasal cavities.

There are a number of ways in which disease in the nasal cavities may affect the intra-ocular structures: (1) through the venous channels; (2) through the arterial supply; (3) through the sensory and motor nerve-supply; (4) through the sympathetic nerves; (5) probably by general absorption of infectious material. Which has been the method in any given case I have not been able to determine; nor have I been able to find in the literature theories advanced which seemed to satisfactorily fit my cases.

In closing let me say that while we have not always been able to point out the channel of infection or the method by which the nasal cavity disease influenced the eye, still ophthalmology owes an enormous debt of gratitude to rhinology, and one of my deep regrets—and in this I know that I voice the sentiments of a multitude—is that in my eye work I have not more thoroughly investigated intranasal conditions.

OPERATIVE TREATMENT OF SUPPURATIVE SINUS DISEASES PRODUCING ORBITAL COMPLICATIONS *

J. H. BRYAN, M.D.
WASHINGTON, D. C.

In 1899 I read a paper before this Association on the accessory sinuses in relation to diseases of the eye. This was probably the first paper on this intricate subject at a joint meeting between the rhinologists and ophthalmologists in America. This subject did not seem to excite much interest on the part of the ophthalmologists at the time; indeed, it is only within the last five or six years that both ophthalmologists and rhinologists have awakened to the fact that the diseases of the accessory sinuses have a most important relation to the orbit and its contents. It is only by a cordial cooperation on the part of ophthalmologists and rhinologists that we are able to arrive at a correct appreciation of the effects of diseased sinuses on the eye, in order that the proper surgical procedures can be adopted to relieve this organ of the many obscure symptoms produced by inflammation in the cavities surrounding the orbit.

In discussing the surgical treatment of diseases of the accessory sinuses producing orbital complications, it is necessary to appreciate thoroughly the intimate relations which these sinuses bear to the walls of the orbit. With so close an anatomic relation between these cavities, it is not difficult to understand why the contents of the orbit should so often be affected by pathologic conditions arising in the sinuses, either from pressure on the walls common to both cavities, from an involvement of the walls in the pathologic process, or by the carrying of septic material through the intercommunication of the veins of the nasal and accessory sinuses with those of the orbital cavity. The sinuses most frequently causing orbital complications are the frontal, ethmoidal and sphenoidal. Disease of the maxillary sinus very rarely acts as a causative factor in the disturbances of the eye, and the disease most frequently met with is the suppurative inflammation.

Among the orbital complications which we are frequently confronted with when the sinuses are abscessed, may be mentioned neuralgia referred to the eye and the supra-orbital nerve; secondary changes in the orbit brought about by mechanical pressure resulting in a change of form in the orbit, in a displacement of the eye-ball with a disturbance of its mobility and function, and in an interference with the flow of the tears; disturbances in the function of the eye, such as dilatation of the pupil and congestion of the papilla, and surcharging of the retinal vessels; narrowing of the field of vision, especially for colors, scotomata, and in severer cases, amblyopia or amaurosis; changes in refraction, abscess of the orbit, lacrimation, exophthalmos, strabismus, mechanical diplopia, mechanical edema with stretching of the upper lid, and retrobulbar neuritis. These symptoms depend on the cavities involved, and the character and intensity of the inflammation existing in them.

After taking into consideration the subjective and objective symptoms, and subjecting the patient to both an ophthalmoscopic and an *x*-ray examination, we are generally able to establish a diagnosis and to determine which cavity or cavities are to be operated on.

INTRANASAL METHODS

The operative treatment may be divided into the intranasal and the external or more radical method. The intranasal method is applicable especially to diseases of the ethmoid cells, and sphenoid cavity. It consists, first, in removing all obstructions, such as polypi and obstructing spurs, and the complete removal of the middle turbinate. This should be done by means of curved scissors or the Luc forceps, under cocain anesthesia. Unless the case is urgent it is better to pack the nasal cavity with gauze until all danger of hemorrhage has passed, which is generally two or three days. We are now in a position to determine the extent of the diseased area in the ethmoid cells. The ethmoid cells are now opened with a rectangular knife similar to one devised by Hajek, and removed by means of a sharp curet or a conchotome. In many cases, if the disease is not too extensive, we are able to remove the affected area, and in this way relieve the pressure on the eye. Ballenger advises the removal of the ethmoid cells and the middle turbinal *en masse*, by means of a knife which he has devised for this purpose. I personally have had no experience with this operation, but he speaks enthusiastically of his method, and, if it is in skilful hands, I can appreciate the great advantages he claims for it.

The sphenoidal sinus can in many cases be approached through the same route after the removal of the middle turbinate, which exposes the anterior wall of the sinus and often brings into view its ostium. A probe passed through this opening is sufficient often times to reveal a diseased condition of the sinus. This opening is rarely large enough to pass an instrument of any size into it; but by means of a small curet it can be enlarged sufficiently to admit a conchotome bent at various angles. Biting upward and downward, nearly the whole of the anterior wall can be removed in a normal sinus. I have in this way opened a large number of abscesses of the sphenoidal sinus and relieved severe pressure on the posterior part of the eye. The tendency, however, is for the opening, no matter how large, to be closed over by a membranous formation requiring frequent removal. Curetting this cavity should be very cautiously done, owing to the danger of injury to the optic nerve or internal carotid artery.

Owing to the irregularities in the sphenoidal sinus, it is not always possible to relieve abscesses in this cavity by the intranasal method. In several instances I have found this cavity to extend outwardly and at the same time dip toward the pterygoid process, and in a preparation which I showed at a meeting of the American Laryngological Association several years ago, it was found to extend some distance down into the internal wing of the pterygoid process. In these cases I have been able to relieve abscesses of the sphenoidal sinus producing eye symptoms, by combining the endonasal method with the antral route. The maxillary sinus is opened through the canine fossa, and then with a gouge and sharp curet the sphenoidal cavity can be entered at its most dependent part, and free drainage established. The frontal sinus can in some instances be opened by the endonasal route after the removal of the middle turbinate and the anterior ethmoidal cells. With a curet, an opening sufficiently large to admit the passage of a cannula can be reamed out, and the cavity washed out daily with a saturated solution of boric acid. If the case is not of long standing this method is sometimes effective. Ingals has practiced this method of late, and uses an electric burr, through which a probe is passed into the sinus as a guide; in his hands, it has been successful. This method, however, is unsatisfactory and dangerous, and can be applicable only to those cases of short duration, in which the cavity is small and not filled with granulation tissue.

---

* Read in the Section on Laryngology, Otology and Rhinology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

EXTERNAL OR RADICAL METHODS

If the intranasal methods fail to relieve the diseased process, then the more radical procedure must be resorted to and the cavity opened from the outside. Within recent years there has been a very marked change in the external operation on the sinuses. In the beginning of my work on these cavities I practiced the Ogston-Luc method, or some modification of it, of opening the frontal sinus exclusively; but owing to several recurrences requiring secondary operations, I abandoned this method and left the frontal wound open and allowed the cavity to fill with granulation tissue. This was a slow and very tedious procedure, but as far as the cure of the frontal sinus disease is concerned, it has been most satisfactory; no recurrences have occurred in any of my patients treated in this way.

From the cosmetic side the results are excellent; in the majority of the cases there has not been the slightest deformity resulting. As far as the cure of the frontal sinus disease is concerned, this method is satisfactory, but it failed to give relief in cases complicated by disease of the ethmoid cells presenting orbital complications, especially in those cases in which the diseased process was located in the anterior and posterior ethmoidal cells and sphenoidal sinus.

Owing to the uncertainty of the above methods in completely relieving all the diseased conditions in the frontal, ethmoidal and sphenoidal sinuses, it is best to adopt the more radical operation proposed by Killian, which in the case of the frontal sinus, has for its purpose a complete removal of all the diseased process, and an obliteration of the cavity, and in the ethmoidal labyrinth a complete removal of all the ethmoidal cells as far back as the sphenoid. The anterior or external route for removal of the ethmoid cells is by far the most radical and satisfactory method we have of reaching suppurative conditions of this bone.

TECHNIC OF THE ANTERIOR OPERATION FOR REMOVAL OF THE ETHMOID CELLS

In this operation, the middle turbinate having been previously removed under cocain, the nasal chamber is packed with cotton plugs as advised by Killian in his operation. The incision is then made, commencing at the inner end of the eyebrow and is carried down along the outer edge and to the full extent of the nasal bone. The periosteum is now incised down to the bone, then stripped from the outer half of the nasal bone and from the whole of the nasal process of the superior maxilla.

The next step in the operation is lifting the lacrimal sac from its bed and detaching the periosteum from the inner wall of the orbit. Great care has to be exercised so as not to tear the sac and cause future trouble. Then with a sharp chisel the outer half of the nasal bone and the whole of the nasal process of the superior maxilla are removed down to the level of the lacrimal groove. This exposes the lacrimal bone and the anterior half of the os planum, which can be opened by means of a small chisel and removed with small bone forceps. This exposes the anterior ethmoidal labyrinth, when with bone forceps, we can with ease, working from before backward, remove completely the whole of the ethmoidal cells, back to the sphenoidal sinus. The plugs are now removed from the nose and the edges of the wound are carefully brought together and sutured, some preferring fine wire; but I believe better cosmetic results are obtained if interrupted sutures of very fine silk are used The incision is protected with either a collodion and iodoform dressing, or, preferably, silver foil, and the eye is bandaged. If there should be any intranasal bleeding, the nose can be packed with small strips of iodoform gauze, which can be removed within twenty-four hours. I have not found this necessary, however.

OGSTON-LUC AND KILLIAN METHODS

I have already mentioned the various external operations for the relief of chronic suppuration in the frontal sinus, viz., the method known as the Ogston-Luc and its modifications, and also the method of opening the sinus and removing a whole or part of its anterior wall and treating the cavity as an open wound. The cavity is gently packed with iodoform gauze, which is removed every second or third day. Granulations form and slowly fill the sinus. Care should be taken not to irrigate the wound, as the granulations are weakened thereby and do not grow rapidly. From four to six weeks is required to fill a fairly large cavity by this method, and in my experience it is fairly satisfactory, as far as a cure is concerned.

I have had no depressions of the anterior wall in my cases, such as is spoken of by some operators. This method is useful only in those cases not complicated with ethmoidal and sphenoidal disease.

The operation best suited for a permanent cure of a suppurative frontal sinusitis, with or without eye complications, and with or without ethmoidal and sphenoidal involvement, is the one known as the radical operation by Killian. This operation has for its purpose a complete removal of all diseased conditions of the frontal, ethmoidal and sphenoidal cavities, the most satisfactory method that we have at our command for the relief of these very serious conditions. In the Killian operation the whole of the anterior wall and the floor of the frontal sinus, which is the stumbling-block in the old methods, are removed.

This operation is a formidable one and fraught with danger, not only to the patient's life, but on account of possible serious injury to the eye and its appendages, and therefore, in order not to bring it into disrepute, it should be undertaken only by those surgically qualified. While this operation may be familiar to most, if not all of you, still a description of it may not be out of place here.

TECHNIC OF KILLIAN OPERATION

The turbinate having been removed at a previous sitting, the patient is anesthetized and placed in a semirecumbent position, at an angle of about forty-five degrees. The nose is then packed with cotton plugs, from four to five being required, according to its capacity. An incision is then made through the whole length of the eyebrow commencing at the external angle. At the inner end, the incision is carried down along the nasal bone to its lower end. Before making the incision through the skin, Killian advises small cross-cuts to be made in order to facilitate an accurate coaptation of the edges of the wound when it is closed. The incision is then carried through the periosteum over the supraorbital ridge and nasal bone, leaving the periosteum over the internal angular process where the bridge is to be made intact. The skin and periosteal tissue are now elevated and forcibly retracted from the frontal bone, and with a V-shaped chisel a furrow is cut through the anterior wall of the sinus, parallel with and about a quarter of an inch above the orbital ridge; an opening sufficiently large to admit of a De Vilbiss bone forceps is made, and with this instrument and various-shaped rongeurs, the whole of the anterior wall above the line of the incision can be removed flush with the frontal bone. The sinus is now completely exposed and all diseased tissue including the mucous lining of the cavity and all septa are removed.

The second stage of this operation corresponds to that described as the external method for opening the ethmoid cells. The periosteum is stripped from the outer half of the nasal bone and the nasal process of the superior maxilla. Then with a specially constructed curved elevator, the lacrimal sac is separated from its bed and the periosteum is detached from the inner wall of the orbit and the anterior two thirds of the os planum. The elevator is then turned upwards, detaching the periosteum from the roof of the orbit. Great care has to be observed not to detach the pulley from its attachment. This can be prevented by having an assistant hold his finger over and a little to the inner side of the supraorbital notch. Gradually, the periosteum is detached from the roof of the orbit as far as its outer angle. Then the outer half of the nasal bone and the nasal process of the superior maxilla are removed by means of a chisel as far as the lower end of the nasal bone, with a V-shaped chisel, and a line is made from the top of the nasal bone upward and outward to the rim of the orbit. This line runs diagonally through the internal angular process of the frontal bone, the upper part of which becomes part of the bridge; the lower part is removed by means of a rongeur. The lacrimal sac and the globe of the eye are retracted outward. Then with bone forceps the lacrimal bone and the os planum are removed, and working from before backward, we can remove the whole of the ethmoidal cells, and the anterior and part of the inferior wall of the sphenoidal sinus. Between the opening made in the frontal wall and the ethmoidal opening, there is a bridge of bone left which is an important factor in reducing the deformity so apt to result. The next step is to remove the roof of the orbit, which can be done with the bone forceps working from below upward, and then standing at the head of the patient and working from above downward, the whole of the floor of the sinus can be removed as far as its outer angle with a chisel. Great care has to be exercised in not detaching the trochlea, otherwise a very uncomfortable complication in the shape of obstinate diplopia results; while this symptom occasionally occurs from slight disturbance of the trochlea, it frequently passes off within a few weeks. Thus far it has happened to me only once, and was very transient in character. A perforated rubber drainage tube or gauze wick is now placed in the floor of the sinus, and brought down through the nose. This drain is allowed to remain from twenty-four to forty-eight hours, when it is removed.

The edges of the periosteum are sutured with catgut, and the external wound closed, great care being exercised to bring the cross-cuts together. The wound is closed either by a subcutaneous suture or numerous interrupted sutures of fine silk. In this latter way I believe we get a finer coaptation of the parts. The wound is then sealed with either silver foil or a 10 per cent. solution of iodoform and collodion. Killian, further to complete the obliteration of the frontal sinus, firmly presses the anterior wall against the posterior. This, however, leaves quite a depression which he afterward corrects by an injection of paraffin. To obviate this depression resulting from the complete removal of the anterior wall of the frontal sinus, Mosher has made a valuable modification of this operation by leaving quite an overhang of the anterior wall of the sinus. A sufficient opening is left so that all diseased conditions and bony septa within the sinus can be removed. I have followed his practice in a number of my more recent operations, and can testify to the greatly improved results over those in the original operation as proposed by Killian.

As has been already stated, the sphenoidal sinus can be opened and completely exenterated in the radical operation on the ethmoid, but it occasionally happens that in certain cases of sphenoidal disease, the sinus dips downward and extends considerably beyond the posterior ethmoidal cells in an outward direction. In these cases I have found certain eye symptoms, such as pain and photophobia, to continue even after the complete opening of the sphenoid in radical ethmoid operation. I have found it necessary in several cases to open the maxillary sinus and remove the diseased bone at the junction of the internal angle of the maxillary and sphenoidal sinuses. Generally speaking, by combining the external route with that through the maxillary sinus, the most obstinate sphenoidal disease can be eradicated.

In conclusion, I would state that in all sinus diseases accompanied by serious eye symptoms, I would give the patient the benefit of the doubt according to the sinus or sinuses involved, and would endeavor to relieve the condition by the endonasal method; but failing in this, I would advise one of the more radical methods as above described. We are more certain of removing all the diseased conditions in the one or more sinuses that may be involved, and the period of convalescence is much shorter than in the older methods, and the danger of relapse is greatly reduced.

818 Seventeenth Street N. W.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. SAUER, ANDREWS AND BRYAN

DR. C. F. WELTY, San Francisco: One case I have had illustrates the point regarding the open dressing of acute cases. My attention was called to that method by a paper written by a New York man, and I followed the advice he gave and had so much deformity that I was sued for malpractice and the suit is still pending. I advised my patient before the operation that such might be the result. We must protect ourselves as well as take care of our patients. Another case I wish to report is an eye case. The patient presented with the eye swollen almost shut. On examination I found polypoid hypertrophy of the middle turbinate and on removing that I found the whole mass of the ethmoid cells full of polypi or material of a polypoid nature. The swelling disappeared. In the course of a month the eye was shut again. I then did a Kilian operation. That is the case I spoke of this morning in which the patient was well within three weeks. Her frontal sinus was so full of polypi that when the mucous membrane was incised they bulged through. I don't think, however, there is such close association between the eye and the nose as we were led to believe a few years ago. Many men were then reporting indefinite eye symptoms that they attributed to possible nasal conditions. I do not do eye work. but I have not had occasion in my nasal work to call in eye men.

Dr. P. Schoonmaker, New York: In the postgraduate hospital we frequently have the eye disturbances Dr. Bryan speaks about. Possibly the preceding speaker has not looked for them. In performing the Kilian operation we often get deformity. And in this connection it is important to remember that with the partial operation there is just as complete drainage as when the entire overhang is removed and there is far less deformity.

Dr. George J. Lund, Los Angeles: During the past year I have had two cases that have bothered me considerably and one especially I would like to refer to. A young lady came to me with pain referred to the nasal region, with rapid loss of vision of the left eye, almost complete within a couple of weeks. Examination of the nasal fossæ revealed absolutely no evidence of nasal disease. I was never able to find any pus present. Ophthalmoscopic examination revealed a choked disk and typical optic neuritis. At that time a friend of mine told me of a similar case and of a procedure he used in that case to help in the diagnosis. He saturated a pledget of cotton with argyrol and placed it under the middle turbinate for twenty minutes. I did this and found a deposit of pus showing on the black substance. The patient was advised to have an operation, but refused and passed out of my care. I heard that she never recovered the use of the eye. I believe she had ethmoid disease and that an operation would have saved her eye. In another case, diagnosticated in the same way as ethmoid trouble, operation was followed by improvement in the vision. That little item in regard to diagnosis has been published and it seems to me very useful. As to the relation between eye and nasal diseases I have been the more impressed with that the longer I have practiced.

Dr. F. P. Emerson, Boston: One class of cases is very frequent, in which there is a history of frequent change of glasses with every irritation of the nose. Often there is in these cases a chronic rhinitis, with every exacerbation of which the ocular symptoms appear. The diagnosis of reflexes in the nose in connection with the eyes requires considerable experience. Every year we find additional foci in connection with these reflexes. There may be only a slight pressure of one turbinate on another or some occlusion of a sinus opening. This blocking may not be accompanied by pus. The last speaker's suggestion is useful. Often the discharge of a little secretion is followed by considerable relief to the patient. It has been my experience that if the anterior sphenoid wall is broken down with the curet considerable reaction occurs and the opening may close up. I have not had so much trouble since I have been biting this out clean and enlarging the opening as far as it seems to go. These operations also solve partially the question of how radical the operation shall be. Our eye cases are certainly some of the worst of our cases of sinus involvement. Often they do not come to us until far advanced and the entire floor of the frontal sinus is necrosed. Then nothing but a radical operation will do any good. We are getting to classify these cases better and to recognize better the cases that require radical operative procedures. I think the eye men are appreciating more and more the relation of the nasal cavities to the eye, and more of these cases are being referred to us. Certainly this symposium will be important in an educational way.

Dr. A. L. Kelsey, Los Angeles: Dr. Bryan spoke of protection of the trochlear sling in the Kilian operation. I would like to know if he has ever seen any permanent disturbance of ocular equilibrium caused by stripping the trochlear sling from its attachment. It was my privilege some years ago to see and examine a number of cases in which operation had been done previously, one case some three weeks and others of longer duration, and in none was there any permanent lack of equilibrium of the muscles.

Dr. A. H. Andrews, Chicago: We have a great many reflex eye symptoms in which we find no definite pathologic condition in the eye. We are more likely to find these in connection with the non-purulent diseases of the accessory cavities, those in which the cavity is filled with serous or mucoserous fluid. The inflammatory conditions of the eyes are more likely to be associated with purulent conditions in the cavities. Dr. Welty says he believes these cases are not so common as he formerly thought and it has been some time since he has referred a case of this sort to an ophthalmologist. If these patients find symptoms on the part of the eye they go to the ophthalmologist themselves. The fact that Dr. Welty has not seen these cases does not indicate that they do not exist. Dr. Lund speaks of introducing a pledget of cotton saturated with argyrol under the middle turbinal. I want to give a word of caution in this regard. If you introduce a pledget of cotton saturated with argyrol or anything else, or even dry cotton, under the turbinal, you will soon find mucus on it, and you must differentiate between mucus and pus or mucopurulent discharge. Dr. Emerson speaks of the frequent change of glasses. There are two explanations of that. One is that no glass relieves the patient and he continues to seek relief by frequent change of glasses. The other is that there is an actual change of refraction in these cases. A writer in the *Journal of Ophthalmology* speaks of scleritis associated with purulent disease of the nose, in which there is an actual change in refraction, due to actual change in the shape of the eye. In Dr. Bryan's paper he speaks of using care in curetting the sphenoid. It is always hazardous curetting the upper and outer part of the sphenoid sinus; never the lower and median wall. I would urge more thorough routine examination of these patients. I suggested some years ago the routine exploration of the sphenoid in all suspicious cases and stated that it could be done in the majority of cases without preliminary surgery, without removing the middle turbinate. With a special bend of the probe, we can get into the sphenoid and with a cannula it can be aspirated or blown out with air and its condition determined.

Dr. J. H. Bryan, Washington, D. C.: The last speaker has made a partial reply to Dr. Welty. I think if he will send his patients to an ophthalmologist he will find many cases in which he has overlooked the eye complications. I submit my patients to the ophthalmologist for a thorough examination. I have in this way found some of the most extraordinary cases, I believe, on record, varying from refractive disturbances to scotomata and paralysis of muscles and I think when the entire record is published it will open the eyes of the ophthalmologists as to the serious effects of the diseases of the accessory sinuses. As to detaching the trochlear from the ridge I have had only one case of diplopia lasting a few weeks. It can, I believe, be avoided largely by having an assistant hold his finger over the attachment. But the diplopia passes away without any serious permanent results.

The Spirit of Scientific Inquiry.—Scientific activity implies, of course, thorough disinterestedness. The investigator asks no favors and renders none. Any intimation that he act as a retainer or special pleader, any hint or suggestion that he restrict his explorations within certain limits, lest he injure cherished traditions, is a step toward the confinement of the free spirit of intellectual inquiry. Rather than surrender that freedom of inquiry or the right of untrammeled announcement of fresh discoveries, men of science have in the past submitted to tortures and painful death, and you may be sure that, if need be, they will be ready to sacrifice themselves again. So exalted is the regard in which the man of science holds the ideal to which his life is devoted that he would find in these words of Fichte his solemn pledge: "To this I am called, to bear witness to the truth. My life, my fortunes, are of little moment; the results of my life are of infinite moment. I am a priest of truth; I am in her pay; I have bound myself to do all things, to venture all things, to suffer all things for her. If I should be persecuted and hated for her sake, if I should even meet death in her service, what wonderful thing is it I shall have done—what but that which I clearly ought to?" —Cannon in *Science*.

GANGRENE OF FINGER CAUSED BY 5 PER CENT. PHENOL OINTMENT

O. F. SCHUSSLER, M.D., and M. A. STERN, M.D.
SOUTH ST. PAUL, MINN.

R. P., an ignorant Hungarian, received a slight scratch on the anterior surface of the second metacarpal (right) about April 17, 1911. He went home and applied a 5 per cent. phenol salve on a closed dressing, according to instructions given him by the druggist who sold the salve. April 24, he reported at my office with finger gangrenous from the distal end of the proximal phalanx to the root of the nail. The gangrene was dry and the finger was completely mummified and as hard as a stone. Moist hot dressings of weak liquor cresolis compositus were applied and by May 1 sloughs were separating. May 20 tendons and periosteum of phalanx had disappeared and May 26 finger was amputated one inch below metacarpophalangeal joint. The bone was soft and mushy and soft tissues devitalized. Recovery was uneventful.

Therapeutics

RINGWORM: TINEA TRICHOPHYTINA

To two very different diseases the name "tinea" has been given: one is tinea favosa, which is caused by the *Achorion schönleinii;* the other is tinea trichophytina, which is caused by the vegetable parasitic fungus trichophyton. It is the latter to which the present remarks will be limited.

The effects of this fungus are usually divided into three subdivisions, according to the particular part of the body affected. When that part of the face on which the beard grows is affected, it is distinguished as tinea barbæ, or ringworm of the beard, or barber's itch. When the hair of the scalp is affected, it is known as tinea tonsurans, or ringworm of the scalp. When other parts of the body are affected it is known as tinea circinata, or ringworm of the body. These three varieties of the disease are also distinguished respectively as tinea trichophytina barbæ, tinea trichophytina capitis, and tinea trichophytina corporis. The same remedies are applicable to the treatment of these three forms of the disease, but the location in which the lesion is found necessitates some difference in their mode of application.

The trichophyton fungus is found and grows in the epidermal layer of the skin. It penetrates into the hair follicles, and also into the root and body of the hair. Its presence in the latter locations renders the application of drugs for its destruction very difficult, and it is on this account that the affection of the hairy scalp and of the beard is especially resistant to treatment.

There are several drugs which are useful in the treatment of the disease when they can be effectively applied. The most important are mercury, hyposulphite of sodium (sodii thiosulphas), tincture of iodin, and sulphur. When there are a few spots on the surface of the body, a useful application is the following:

℞	Gm. or c.c.			
Hydrargyri chloridi corrosivi		10		gr.ii
Glycerini	5		or	fl.ʒii
Aquæ	ad 50			ad fl.℥ii

M. et Sig.—Shake, and rub thoroughly into the lesion, twice a day.

The application of this lotion, or in fact of any remedy, should be preceded by a thorough scrubbing of the affected parts with hot water and soap, preferably soft soap or green soap. When the patient is a young child, care should be exercised not to apply too strong a lotion and not to apply it to too extensive a portion of the body, for too liberal applications of strong mercurial lotions may cause mercurial poisoning.

Another very effective remedy for the trichophyton as well as for other vegetable parasitic growths is the hyposulphite of sodium. This may be used in the strength of 15 to 20 per cent. in water.

If one prefers to use an ointment—and ointments are often exceedingly useful because watery preparations do not easily penetrate the skin—an efficient ointment is the official unguentum hydrargyri ammoniati. This ointment is 10 per cent. in strength. If there are many spots of disease, or the skin is tender, it is well to dilute it with an equal part of lard or petroleum fat, as:

℞	Gm.		
Unguenti hydrargyri ammoniati	15	or	
Adipis benzoinati	15		āā ℥ss

M. et Sig.—Apply to spots twice a day.

Sulphur may be used in ointment or lotion, but is not so efficient.

If the condition is chronic, and these washes and lotions do not prove effective, the patches may be painted with tincture of iodin. This may be repeated every day for several days until the inflammation becomes so great that the application causes objectionable discomfort

Ointments containing chrysarobin (incorrectly called chrysophanic acid), or pyrogallol (pyrogallic acid) are effective, but should not often be used on account of the fact that they stain the skin and clothing, and sometimes cause considerable inflammation.

When the scalp is affected and the fungus has penetrated the hair follicles, it is often difficult to apply these remedies effectively. It is generally wise to cut the hair short, and even to shave the head. The hairs will usually be found broken, and it is generally desirable to remove as many of the hairs as possible before applying the remedy. The affected parts should then be thoroughly washed with soap and water, and lotions of corrosive sublimate or of the thiosulphate of sodium may be used.

In cases which prove resistant to other treatment, it is sometimes necessary to attempt a cure by producing an active inflammation of the affected part. This may be accomplished by painting the part with tincture of iodin, as has been already mentioned; or croton oil may be rubbed into the affected part; or the part may be painted with cantharidated collodion so as to produce a blister. This will often result in a rapid cure.

The *x*-ray has been used as a germicidal application, and as a promoter of a mild dermatitis (often a forerunner of a cure) in all parts of the body, and with frequent reports of success. The hair, if the ray is used on hairy parts, falls out, but seems to generally soon return.

When the beard is affected, the removal of the hairs can generally be more thoroughly accomplished, and then the various applications already enumerated may be used.

Poultices have been suggested for the purpose of softening the skin and cleaning off the crusts, but they are generally undesirable, as the moist heat favors the growth of the fungus.

These cases are often very obstinate, and treatment must sometimes be carried on, intermittently, for weeks. It often happens that an apparent cure results while a few of the fungi still remain in the skin without showing any evidence of their presence. Consequently, cases should be kept under observation for some time after a cure is apparently complete, and if any evidence of a return of the disease appears, the treatment should be renewed.

This disease appears more frequently in children than in adults, and the growth of the fungus seems to be favored by high temperature and by moisture. The disease is contagious, and is readily passed from one individual to another. Where considerable numbers of people associate intimately together great care should be observed to prevent one contracting the disease from another. The use of combs, brushes, towels and clothing by different individuals in common should be strictly forbidden, especially when the existence of a single case among a number of children, as for instance in a large family or in a school, is known. It seems likely that with the extension of medical inspection to children in the public schools and with sanitary barber shops. this disease will, in a few years, become exceedingly rare.

INGROWING TOE-NAIL

This rather common, always troublesome, and frequently obstinate affection is usually considered as belonging in the domain of the surgeon, but the general practitioner is often consulted first, and the patient frequently objects to operative treatment. When he does so, he is entitled to receive from his physician such less radical treatment as will increase his comfort and, if possible, cure the disease.

This condition may be the result of an hypertrophy of the nail, which may become thickened and increase laterally so as to become imbedded in the tissues at the side of the nail. More commonly the trouble is due to the patient's carelessness in not keeping his feet clean, in not paying proper attention to the condition of his nails, and in wearing too tight or otherwise ill-fitting shoes. The condition is characterized by swelling, with congestion and inflammation of the tissues, accompanied with considerable, and often intolerable pain.

When it is decided to apply palliative treatment and there is considerable swelling and inflammation in the soft parts, attended with pain, the toe may be poulticed for twenty-four hours with an antiseptic wet dressing. A very efficient and satisfactory antiseptic wet dressing is one of alcohol 1 part and hot water 4 parts. A napkin or a large bunch of loose gauze is thoroughly soaked in this solution and applied about the toe and the part of the foot affected; then the foot and application is surrounded by rubber tissue or oil silk, and a retaining bandage applied. This dressing may be reapplied every six hours. This application will relieve the pain, swelling and inflammation, and soften the nail. It may be preferable to apply constantly for twenty-four or forty-eight hours a warm 1 per cent. solution of phenol (carbolic acid). A strong solution of hydrogen peroxid, 1 part to 4 of water, may also be used as a dressing. The patient, of course, must be quiet in bed, or in a chair with his leg and foot resting on a pillow on another chair.

After these wet dressings have been applied constantly for one or two days, the plan of treatment may be somewhat changed. At each dressing the toe should be allowed to soak in a bowl of hot water for ten minutes. The water may contain 1-per cent. of phenol, or a 1 to 2,000 solution of corrosive sublimate. In this way both the nail and the surrounding tissues are softened and thoroughly cleansed. If there are granulations present, these should be touched with a stick of nitrate of silver (lunar caustic), or with a swab wet with a 25 per cent. solution of nitrate of silver.

An effort should be made to retract the soft tissues from the side of the nail, and as this is accomplished a small piece of sterile gauze or sterile linen should be placed under the edge of the nail between it and the soft tissues. Narrow strips of adhesive plaster may then be applied transversely to the nail and around the toe so as to exert pressure on the soft parts in such a direction as to draw them away from the side of the nail.

After this treatment has been followed for some days, the condition of the parts will usually be found to be greatly improved. The pain, inflammation and swelling of the soft parts will have disappeared, and the edge of the nail will not be overlapped by the soft parts.

By this time the patient wishes to walk about, and then he must be provided with a suitable shoe which will be large enough not to press injuriously on the toe. The toe should also be wrapped in absorbent cotton so as to be protected from the moderate pressure which is more or less inevitable.

Instead of this treatment, some prefer to touch the granulating point with a drop of pure phenol.

In other cases it may be preferable to apply a drying and antiseptic powder, as:

℞	Gm.		
Sodii salicylatis	50	or	gr.x
Acidi borici	50		℥ii

M. et Sig.—Use externally.

Or,

℞	Gm.		
Sodii salicylatis	50		gr.x
Mentholis	2	or	ʒss
Acidi borici	ad 50		ad ℥ii

M. et Sig.—Use externally.

Or,

℞	Gm.		
Sodii salicylatis	25		gr.v
Aluminis exsiccati	5	or	ʒiss
Acidi borici	ad 25		ad ℥i

M. et Sig.—Use externally.

If these simple methods of treatment do not prove effective, a more radical surgical procedure must be resorted to. In this case it is necessary to give the patient a general anesthetic, or to apply sufficient local anesthesia. The congested and swollen soft parts may then be removed with a sharp knife and the raw surface allowed to heal by granulation under suitable dressings. Or, the part of the nail which has grown into the soft parts may be removed by incision and avulsion, along with the matrix beneath it, which will prevent further growth of the nail, and leave the parts free from the irritation of the edge of the nail. In other cases the whole nail may be removed and a part, or the whole, of the matrix so that no part of the nail will grow again.

Infection of Wounds.—The nearer we can approach, without unreasonably delaying the operation, to four clean hands, rubber-gloved, the wiser. (They must be clean, absolutely, because of the occasional tearing or cutting of a glove finger.) With one excellently trained player in the treble, the surgeon takes the bass, making the *magnum opus* a four-handed piece; and there will be, indeed, few or no false notes while this music lasts—certainly a triumph, remembering that the musicians are playing while gloved. To-day, with rare exceptions, infection in a clean wound should mean shame to the surgeon.—Dawbarn in *Medical Record.*

GANGRENE OF FINGER CAUSED BY 5 PER CENT. PHENOL OINTMENT

O. F. SCHUSSLER, M.D., and M. A. STERN, M.D.
SOUTH ST. PAUL, MINN.

R. P., an ignorant Hungarian, received a slight scratch on the anterior surface of the second metacarpal (right) about April 17, 1911. He went home and applied a 5 per cent. phenol salve on a closed dressing, according to instructions given him by the druggist who sold the salve. April 24, he reported at my office with finger gangrenous from the distal end of the proximal phalanx to the root of the nail. The gangrene was dry and the finger was completely mummified and as hard as a stone. Moist hot dressings of weak liquor cresolis compositus were applied and by May 1 sloughs were separating. May 20 tendons and periosteum of phalanx had disappeared and May 26 finger was amputated one inch below metacarpophalangeal joint. The bone was soft and mushy and soft tissues devitalized. Recovery was uneventful.

Therapeutics

RINGWORM: TINEA TRICHOPHYTINA

To two very different diseases the name "tinea" has been given: one is tinea favosa, which is caused by the *Achorion schönleinii;* the other is tinea trichophytina, which is caused by the vegetable parasitic fungus trichophyton. It is the latter to which the present remarks will be limited.

The effects of this fungus are usually divided into three subdivisions, according to the particular part of the body affected. When that part of the face on which the beard grows is affected, it is distinguished as tinea barbæ, or ringworm of the beard, or barber's itch. When the hair of the scalp is affected, it is known as tinea tonsurans, or ringworm of the scalp. When other parts of the body are affected it is known as tinea circinata, or ringworm of the body. These three varieties of the disease are also distinguished respectively as tinea trichophytina barbæ, tinea trichophytina capitis, and tinea trichophytina corporis. The same remedies are applicable to the treatment of these three forms of the disease, but the location in which the lesion is found necessitates some difference in their mode of application.

The trichophyton fungus is found and grows in the epidermal layer of the skin. It penetrates into the hair follicles, and also into the root and body of the hair. Its presence in the latter locations renders the application of drugs for its destruction very difficult, and it is on this account that the affection of the hairy scalp and of the beard is especially resistant to treatment.

There are several drugs which are useful in the treatment of the disease when they can be effectively applied. The most important are mercury, hyposulphite of sodium (sodii thiosulphas), tincture of iodin, and sulphur. When there are a few spots on the surface of the body, a useful application is the following:

℞	Gm. or c.c.		
Hydrargyri chloridi corrosivi......	10		gr.ii
Glycerini	5	or	fl.ʒii
Aquæ	ad 50		ad fl.ʒii

M. et Sig.—Shake, and rub thoroughly into the lesion, twice a day.

The application of this lotion, or in fact of any remedy, should be preceded by a thorough scrubbing of the affected parts with hot water and soap, preferably soft soap or green soap. When the patient is a young child, care should be exercised not to apply too strong a lotion and not to apply it to too extensive a portio the body, for too liberal applications of strong merc lotions may cause mercurial poisoning.

Another very effective remedy for the trichoph as well as for other vegetable parasitic growths is hyposulphite of sodium. This may be used in strength of 15 to 20 per cent. in water.

If one prefers to use an ointment—and ointment- often exceedingly useful because watery preparation not easily penetrate the skin—an efficient ointmen the official unguentum hydrargyri ammoniati. ointment is 10 per cent. in strength. If there are n spots of disease, or the skin is tender, it is well to di it with an equal part of lard or petroleum fat, as:

℞	Gm.		
Unguenti hydrargyri ammoniati....	15	or	
Adipis benzoinati	15		ā

M. et Sig.—Apply to spots twice a day.

Sulphur may be used in ointment or lotion, bu not so efficient.

If the condition is chronic, and these washes lotions do not prove effective, the patches may be pai with tincture of iodin. This may be repeated every for several days until the inflammation becomes so that the application causes objectionable discomfor

Ointments containing chrysarobin (incorrectly c chrysophanic acid), or pyrogallol (pyrogallic acid effective, but should not often be used on account o fact that they stain the skin and clothing, and times cause considerable inflammation.

When the scalp is affected and the fungus has trated the hair follicles, it is often difficult to these remedies effectively. It is generally wise t the hair short, and even to shave the head. The will usually be found broken, and it is generally able to remove as many of the hairs as possible applying the remedy. The affected parts shoul be thoroughly washed with soap and water, and of corrosive sublimate or of the thiosulphate of may be used.

In cases which prove resistant to other treatn is sometimes necessary to attempt a cure by pr an active inflammation of the affected part. T be accomplished by painting the part with tin iodin, as has been already mentioned; or croton be rubbed into the affected part; or the part painted with cantharidated collodion so as to p blister. This will often result in a rapid cure.

The *x*-ray has been used as a germicidal ap and as a promoter of a mild dermatitis (oft runner of a cure) in all parts of the body, frequent reports of success. The hair, if t used on hairy parts, falls out, but seems to soon return.

When the beard is affected, the removal o can generally be more thoroughly accomp then the various applications already enum be used.

Poultices have been suggested for the softening the skin and cleaning off the cr are generally undesirable, as the moist h growth of the fungus.

These cases are often very obstinate, must sometimes be carried on, intermitt It often happens that an apparent cur few of the fungi still remain in the s ing any evidence of their presence.

should be kept under observation for some time after a cure is apparently complete, and if any evidence of a return of the disease appears, the treatment should be renewed.

This disease appears more frequently in children than in adults, and the growth of the fungus seems to be favored by high temperature and by moisture. The disease is contagious, and is readily passed from one individual to another. Where considerable numbers of people associate intimately together great care should be observed to prevent one contracting the disease from another. The use of combs, brushes, towels and clothing by different individuals in common should be strictly forbidden, especially when the existence of a single case among a number of children, as for instance in a large family or in a school, is known. It seems likely that with the extension of medical inspection to children in the public schools and with sanitary barber shops. this disease will, in a few years, become exceedingly rare.

INGROWING TOE-NAIL

This rather common, always troublesome, and frequently obstinate affection is usually considered as belonging in the domain of the surgeon, but the general practitioner is often consulted first, and the patient frequently objects to operative treatment. When he does so, he is entitled to receive from his physician such less radical treatment as will increase his comfort and, if possible, cure the disease.

This condition may be the result of an hypertrophy of the nail, which may become thickened and increase laterally so as to become imbedded in the tissues at the side of the nail. More commonly the trouble is due to the patient's carelessness in not keeping his feet clean, in not paying proper attention to the condition of his nails, and in wearing too tight or otherwise ill-fitting shoes. The condition is characterized by swelling, with congestion and inflammation of the tissues, accompanied with considerable, and often intolerable pain.

When it is decided to apply palliative treatment and there is considerable swelling and inflammation in the soft parts, attended with pain, the toe may be poulticed for twenty-four hours with an antiseptic wet dressing. A very efficient and satisfactory antiseptic wet dressing is one of alcohol 1 part and hot water 4 parts. A napkin or a large bunch of loose gauze is thoroughly soaked in this solution and applied about the toe and the part of the foot affected; then the foot and application is surrounded by rubber tissue or oil silk, and a retaining bandage applied. This dressing may be reapplied every six hours. This application will relieve the pain, swelling and inflammation, and soften the nail. It may be preferable to apply constantly for twenty-four or forty-eight hours a warm 1 per cent. solution of phenol (carbolic acid). A strong solution of hydrogen peroxid, 1 part to 4 of water, may also be used as a dressing. The patient, of course, must be quiet in bed, or in a chair with his leg and foot resting on a pillow on another chair.

After these wet dressings have been applied constantly for one or two days, the plan of treatment may be somewhat changed. At each dressing the toe should be allowed to soak in a bowl of hot water for ten minutes. The water may contain 1-per cent. of phenol, or a 1 to 2,000 solution of corrosive sublimate. In this way both the nail and the surrounding tissues are softened and thoroughly cleansed. If there are granulations present, these should be touched with a stick of nitrate of silver (lunar caustic), or with a swab wet with a 25 per cent. solution of nitrate of silver.

An effort should be made to retract the soft tissues from the side of the nail, and as this is accomplished a small piece of sterile gauze or sterile linen should be placed under the edge of the nail between it and the soft tissues. Narrow strips of adhesive plaster may then be applied transversely to the nail and around the toe so as to exert pressure on the soft parts in such a direction as to draw them away from the side of the nail.

After this treatment has been followed for some days, the condition of the parts will usually be found to be greatly improved. The pain, inflammation and swelling of the soft parts will have disappeared, and the edge of the nail will not be overlapped by the soft parts.

By this time the patient wishes to walk about, and then he must be provided with a suitable shoe which will be large enough not to press injuriously on the toe. The toe should also be wrapped in absorbent cotton so as to be protected from the moderate pressure which is more or less inevitable.

Instead of this treatment, some prefer to touch the granulating point with a drop of pure phenol.

In other cases it may be preferable to apply a drying and antiseptic powder, as:

℞	Gm.			
Sodii salicylatis		50	or	gr.x
Acidi borici	50			℥ii

M. et Sig.—Use externally.

Or,

℞	Gm.			
Sodii salicylatis		50		gr.x
Mentholis	2		or	ʒss
Acidi borici	ad 50			ad ℥ii

M. et Sig.—Use externally.

Or,

℞	Gm.			
Sodii salicylatis		25		gr.v
Aluminis exsiccati	5		or	ʒiss
Acidi borici	ad 25			ad ℥i

M. et Sig.—Use externally.

If these simple methods of treatment do not prove effective, a more radical surgical procedure must be resorted to. In this case it is necessary to give the patient a general anesthetic, or to apply sufficient local anesthesia. The congested and swollen soft parts may then be removed with a sharp knife and the raw surface allowed to heal by granulation under suitable dressings. Or, the part of the nail which has grown into the soft parts may be removed by incision and avulsion, along with the matrix beneath it, which will prevent further growth of the nail, and leave the parts free from the irritation of the edge of the nail. In other cases the whole nail may be removed and a part, or the whole, of the matrix so that no part of the nail will grow again.

Infection of Wounds.—The nearer we can approach, without unreasonably delaying the operation, to four clean hands, rubber-gloved, the wiser. (They must be clean, *absolutely*, because of the occasional tearing or cutting of a glove finger.) With one excellently trained player in the treble, the surgeon takes the bass, making the *magnum opus* a four-handed piece; and there will be, indeed, few or no false notes while this music lasts—certainly a triumph, remembering that the musicians are playing while *gloved*. To-day, with rare exceptions, infection in a clean wound should mean shame to the surgeon.—Dawbarn in *Medical Record*.

University of Illinois College of Medicine, Honore and Congress Streets.—Organized in 1882 as the College of Physicians and Surgeons. The first class graduated in 1883. It became the Medical Department of the University of Illinois by affiliation in 1896 and an integral part in 1910. Present title assumed in 1911. The American Medical Missionary College was merged into it in 1910. The faculty is composed of 44 professors, 95 assistants and instructors, a total of 139. The fees are $155 each for the first two years, $150 for the third, and $160 for the fourth year. The Dean is Dr. William E. Quine. Total registration for 1910-11 was 508; graduates, 94. The thirtieth session begins Sept. 26, 1911, and ends June 4, 1912.

Chicago College of Medicine and Surgery, 706 South Lincoln Street.—Organized in 1901 as the American College of Medicine and Surgery (Chicago Eclectic Medical College). The latter part of the name was dropped in 1902 and it became the Medical Department of Valparaiso University. Eclecticism was dropped in 1905. The name was changed to the above in 1907. The course covers four years of eight months each. The faculty consists of 39 professors and 34 lecturers and assistants, a total of 73. The total fees for each of the four years, respectively, are $120, $110, $100 and $100. The Registrar is Dr. G. E. Wyneken. The total registration for 1910-11 was 630; graduates, 86. The eleventh session begins Sept. 26, 1911, and ends May 20, 1912.

Hahnemann Medical College and Hospital of Chicago, 2811 Cottage Grove Avenue.—Organized in 1859. The first class was graduated in 1861. The faculty includes 38 professors and 46 lecturers, assistants, etc., a total of 84. The course extends over four years of eight months each. The tuition fees are $100 each year. The Registrar is Dr. W. Henry Wilson. The total registration for 1910-11 was 107; graduates, 22. The fifty-second session begins Sept. 27, 1911, and ends May 25, 1912.

Hering Medical College, Homeopathic, Wood and York Streets.—Organized in 1892. The first class graduated in 1893. The faculty consists of 28 professors and 22 assistants, instructors, etc., a total of 50. The tuition fees for each of the four years respectively are $115, $105, $110 and $100. The Dean is Dr. Robert N. Morris. The total registration for 1910-11 was 40; graduates, 7. The next session begins Sept. 26, 1911, and ends June 16, 1912.

Bennett Medical College, Fulton and Ada Streets, Medical Department of Loyola University.—Organized in 1868 as the Bennett College of Eclectic Medicine and Surgery. Dropped Eclecticism in 1909. In 1910 it united with the Illinois Medical College and became by affiliation the Medical Department of Loyola University. The first class graduated in 1870. The faculty numbers 102. The course covers four years of thirty weeks each. Fees for each year are $125, with a matriculation fee, paid once, of $5. The President is Dr. John D. Robertson. The total registration for the two colleges in 1910-11 was 283; graduates, 56. The next session begins Sept. 26, 1911, and ends June 13, 1912.

Jenner Medical College, an afternoon and evening school, located at 223 West Washington Street.—Organized in 1892. Classes were graduated in 1896 and in all subsequent years. The faculty numbers 42. The Secretary is Dr. John D. MacKellar. Total registration for 1910-11 was 117; graduates, 9. The next session begins Sept. 5, 1911, and ends June 15, 1912.

INDIANA

Indiana, population 2,700,876, has one medical college, the Indiana University School of Medicine, located at Indianapolis, a city of 233,650 people, except that the work of the first year is offered also at Bloomington, the seat of the University.

Bloomington and Indianapolis

Indiana University School of Medicine.—Organized in 1893, medical course until 1905. In 1907, by union with the State College of Physicians and Surgeons, the complete course in medicine was offered. In 1908 the Indiana Medical College, which was formed in 1907 by the merger of the Medical College of Indiana (organized in 1869) and the Fort Wayne College of Medicine (organized in 1879) merged into it. The faculty consists of 100 professors and 89 lecturers, associates and assistants, a total of 189. Two years of collegiate work are required for admission. The work of the first year may be taken either at Bloomington or at Indianapolis. The work of the other three years is all done at Indianapolis. A fifth optional year leading to the "M.D. *cum laude*" has been added. The Secretary at Bloomington is Dr. B. D. Myers; the Dean is Dr. Charles P. Emerson, Indianapolis. The total registration for 1910-11 was 188; graduates, 52. The next session begins Sept. 21, 1911, and ends June 18, 1912.

IOWA

Iowa, population 2,224,771, has three medical colleges. The College of Medicine of the State University of Iowa and the College of Homeopathic Medicine of the State University of Iowa are located in Iowa City, population 10,091. In Des Moines, population 86,368, is the College of Medicine of Drake University.

Des Moines

Drake University College of Medicine.—First two years given on the University Campus, University Avenue, between Twenty-fifth and Twenty-eighth Streets, the clinical years at Fourth and Center Streets. Organized in 1881 as the Iowa Eclectic Medical College. The first class graduated in 1882. In 1887 it merged into the Iowa College of Physicians and Surgeons and became the Medical Department of Drake University. In 1903 it took its present title. The faculty consists of 20 professors and 23 assistants, lecturers, etc., a total of 43. Two years of collegiate work, including courses in physics, chemistry and biology, are required for admission. The work covers four years of nine months each. The total fees are $165 each year. The Dean is Dr. William Wilson Pearson. The total registration for 1910-11 was 72; graduates, 14. The twenty-ninth session begins Sept. 20, 1911, and ends June 12, 1912.

Iowa City

State University of Iowa College of Medicine. University Campus.—Organized in 1869. First session began in 1870. First class graduated in 1871. The faculty is made up of 15 professors, 25 lecturers, demonstrators and assistants, a total of 40. Two years of collegiate work, including courses in physics, chemistry and biology, are required for admission. The course of study covers four years of thirty-six weeks each. Total fees for each year are $50 plus a matriculation fee of $10 paid but once and a graduation fee of $10. The Dean is Dr. James R. Guthrie, Dubuque. Total number of students registered for 1910-11 was 118; graduates, 24. The forty-second session begins September 18, 1911, and ends June 12, 1912.

State University of Iowa College of Homeopathic Medicine.—Organized in 1877. The first class graduated in 1878. The faculty is composed of 11 professors and 19 lecturers and assistants, a total of 30. The work of the first two years is taken in classes with the students of the College of Medicine of the State University of Iowa, and it has the same entrance requirements. The fees are $50 each year, plus a matriculation fee of $10, paid but once, and a graduation fee of $10. The Dean is Dr. George Royal. Total registration for 1910-11 was 18; graduates, 3. The thirty-fourth session begins Sept. 18, 1911, and ends June 2, 1912.

KANSAS

Population 1,690,949, has two medical colleges. Kansas Medical College is in Topeka, population 43,684. The School of Medicine of the University of Kansas gives its first two years in Lawrence, population 12,915, and the last two years in Rosedale, a suburb of the two Kansas Cities, which together have a population of 330,662.

Lawrence and Kansas City

University of Kansas School of Medicine.—Organized in 1880. In 1905 it merged with the Kansas City (Mo.) Medical College, founded in 1869, the College of Physicians and Surgeons, founded in 1894, and the Medico-Chirurgical College, founded in 1897. The faculty, including lecturers and clinical assistants, numbers 84. The requirements for admission are two years of collegiate work. The course covers four years of nine months each. The total fees are, for the first two years, $60 per year (and for non-residents of the state, $80); for the last two years, $100 and $110, respectively. The Dean at Lawrence is Dr. Mervin T. Sudler. The Dean at Kansas City is Dr. George Howard Hoxie. The total registration for 1910-11 was 85; graduates, 19. The thirty-second session begins Sept. 13, 1911, and ends June 5, 1912.

Topeka

Kansas Medical College, 521 Quincy Street.—Organized in 1890. The first class graduated in 1892. It has been the Medical Department of Washburn College since 1903. It has a faculty of 31 professors and 10 lecturers and assistants, a total of 41. The course covers four years of nine months each. Fees, $100 yearly. Matriculation fee of $5 paid but once. The Dean is Dr. William E. McVey. Total registration for 1910-11 was 52; graduates, 10. The twenty-second session begins Sept. 12, 1911, and ends June 5, 1912.

KENTUCKY

Kentucky, population 2,289,905, has two medical colleges. They are both situated in Louisville, a city of 223,928 inhabitants, and are as follows: University of Louisville Medical Department and Louisville National Medical College.

Louisville

University of Louisville Medical Department, Eighth and Chestnut Streets.—Organized in 1837 as the Louisville Medical Institute. The first class graduated in 1838, and a class graduated in each subsequent year except 1863. In 1846 the present name was assumed. In 1907 it absorbed the Kentucky University Medical Department. In 1908 it absorbed the Louisville Medical College, the Hospital College of Medicine and the Kentucky School of Medicine. It has a faculty of 42 professors and 50 lecturers and assistants, a total of 92. The course covers four years of thirty-two weeks each. The fees are $105 each year; graduation fee, $25. The Dean is Dr. W. Edward Grant. The total registration for 1910-11 was 447; graduates, 159. The next session begins Oct. 2, 1911, and ends May 30, 1912.

Louisville National Medical College.—Colored. 112 West Green Street.—Organized in 1888. The first class graduated in 1889. The faculty numbers 23. The course covers four years of seven months each. The fees are $60, $55, $55 and $75 for the four years, respectively. The Dean is Dr. E. S. Porter. Total registration for 1910-11 was 25; graduates, 10. The next session begins Oct. 2, 1911, and ends May 18, 1912.

LOUISIANA

Louisiana, having a population of 1,656,388, contains one medical college, the Medical Department of the Tulane University of Louisiana, situated in New Orleans, a city of 339,075.

New Orleans

Medical Department of the Tulane University of Louisiana. University Campus and 1551 Canal Street.—Organized in 1834 as the Medical College of Louisiana. Classes were graduated in 1835 and in all subsequent years, except 1863-65, inclusive. It was transferred to Medical Department of the University of Louisiana in 1847 and became the Medical Department of the Tulane University in 1884. The faculty numbers 93. The course covers four years of thirty-two weeks each. One year of collegiate work is required for admission. Total fees are $180 per year; graduation fee, $30. The Dean is Dr. Isadore Dyer. The total registration for 1910-11 was 379; graduates, 90. The seventy-eighth session begins Sept. 29, 1911, and ends May 29, 1912.

MAINE

Maine, population 742,371, has one medical college, located in Brunswick and Portland, the latter having a population of 58,571.

Brunswick-Portland

Medical School of Maine.. The medical department of Bowdoin College. The first two years are given at Bowdoin College, Brunswick, the last two at Portland, building located on Chadwick Street.—Organized in 1820. The first class graduated in 1820. The faculty numbers 41. The course covers four years of eight months each. The total fees are $120 for the first year and $110 for each of the other three years. The Dean is Dr. Alfred Mitchell, Brunswick. Total number of students in 1910-11 was 67; graduates, 13. The ninety-first session begins Oct. 12, 1911, and ends June 19, 1912.

MARYLAND

Maryland, with a population of 1,295,346, contains five medical colleges, all located in Baltimore, a city with 558,485 inhabitants. They are as follows: Johns Hopkins University Medical Department, School of Medicine of the University of Maryland, College of Physicians and Surgeons, Baltimore Medical College and Maryland Medical College.

Baltimore

Johns Hopkins University Medical Department, Washington and Monument Streets.—Organized in 1893. The first class graduated in 1897. The faculty consists of 23 professors and 89 clinical professors, etc., a total of 112. The requirements for admission demand that the applicant either has (a) completed the chemical-biologic course which leads to the A.B. degree in the university or (b) graduated at an approved college or scientific school and has a knowledge of French and German, physics, chemistry and biology, such as may be obtained from a year's course. The course extends over four years of eight and one-half months each. The charge for tuition is $200 per annum. The Dean is Dr. J. Whitridge Williams. Total registration for 1910-11 was 347; graduates, 85. The nineteenth session begins Oct. 3, 1911, and ends June 11, 1912.

College of Physicians and Surgeons, Calvert and Saratoga Streets.—Organized in 1872. The first class graduated in 1873. In 1878 it united with Washington University School of Medicine. The faculty numbers 62. The work covers four years of eight months each. Total fees are $155 for each of the first three years and $185 for the fourth year. The Dean is Dr. Charles F. Bevan. The total number of students registered in 1910-11 was 289; graduates, 57. The fortieth session begins Oct. 2, 1911, and ends June 16, 1912.

University of Maryland School of Medicine, Lombard and Greene Streets. Organized in 1807 as the College of Medicine of Maryland. The first class graduated in 1810. In 1812 it became the University of Maryland School of Medicine. The faculty numbers 62. The course covers four years of eight months each. The total fees are $155 each year; graduation fee, $30. The Dean is Dr. R. Dorsey Coale. The total number of students registered in 1910-11 was 324; graduates, 70. The 105th session begins Oct. 2, 1911, and ends June 1, 1912.

Baltimore Medical College, Madison Street and Linden Avenue.—Organized in 1881. The first class graduated in 1882. The faculty numbers 75. The course covers four years of eight months each. Total fees for the first three years are $125 per year; for the fourth year, $155. The Dean is Dr. David Streett. The total number of students registered in 1910-11 was 205; graduates, 48. The thirtieth session begins Sept. 20, 1911, and ends June 1, 1912.

Maryland Medical College, 1114 West Baltimore Street.—Organized in 1898. The first class graduated in 1899. The faculty numbers 39. The course covers four years of eight months each. Total fees for the four years, respectively, are $111, $111, $105 and $135. The Dean is Dr. W. S. Smith. The total registration for 1910-11 was 167; graduates, 65. The next session begins Oct. 2, 1911, and ends June 1, 1912.

MASSACHUSETTS

Massachusetts, population 3,366,416, has four medical colleges: Medical School of Harvard University, Boston University School of Medicine, College of Physicians and Surgeons and Tufts College Medical School. They are all situated in Boston, a city of 670,585.

Boston

Medical School of Harvard University, Longwood Avenue.—Organized in 1782. The first class graduated in 1788. It has a faculty of 30 professors and 146 associates, assistants, etc., a total of 176. Candidates for admission "must present a degree in arts, literature, philosophy or science from a recognized college or scientific school, with the exception of such persons as may be admitted by special vote of the faculty." The session is four years of eight months each. Fees: Matriculation, $5; tuition, $200 each year. The Dean is Dr. Henry A. Christian. The total registration for 1910-11 was 264; graduates, 87. The 130th session begins Sept. 28, 1911, and ends June 28, 1912.

Boston University School of Medicine, 80 East Concord Street.—Organized in 1873. In 1874 the New England Female Medical College, founded in 1848, was merged into it. The first class graduated in 1874. The faculty includes 25 professors, 49 associates etc., a total of 74. The course covers four years of eight months each. Total fees for the first, second and third years, $127 each, and for the last year $155. The Dean is Dr. John P. Sutherland, 295 Commonwealth Avenue. Total registration for 1910-11 was 86; graduates, 16. The thirty-ninth session begins Oct. 5, 1911, and ends June 6, 1912.

Tufts College Medical School, 416 Huntington Avenue.—Organized in 1893 as the Medical Department of Tufts College. The first class graduated in 1894. It has a faculty of 22 professors and 94 assistants, lecturers, etc., a total of 116. The course covers four years of eight months each. The total fees are $155 each year. The Secretary is Dr. Frederic M. Briggs, 416 Huntington Avenue Total number of students for 1910-11 was 379; graduates, 71. The eighteenth session begins Sept. 27, 1911, and ends June 1, 1912.

College of Physicians and Surgeons, 517 Shawmut Avenue.—Organized in 1880. The first class graduated in 1882. The college announcement gives the names of 226 "matriculants and applicants" for the session of 1909-10, which included both dental and medical students. The same total is given for 1910-11, but 198 are reported as having "registered" for the medical work. The names of some of the students who graduated in 1910 appear in the announcements of this school from six to nine years! There were 23 medical graduates reported in 1911. The Dean is Dr. Thomas D. Crothers. *This college is not recognized by the Massachusetts Medical Society.*

MICHIGAN

Michigan, population 2,810,173, has four medical colleges. Two of these, the University of Michigan Department of Medicine and Surgery and the Homeopathic College of the University of Michigan, are located at Ann Arbor, a city of 14,817 people. Detroit, a city of 465,766 inhabitants, contains two medical colleges, the Detroit College of Medicine and the Detroit Homeopathic College.

Ann Arbor

University of Michigan Department of Medicine and Surgery.—Organized in 1850. The first class graduated in 1851. It has a faculty composed of 33 professors, 38 associates, instructors, etc., a total of 71. The entrance requirements are two years of college work, including courses in chemistry, physics and biology, with laboratory work, and a reading knowledge of one modern language. The curriculum embraces four years of nine months each. The total fees for Michigan students for the entire course of four years is $350 and for others about $400. The Dean is Dr. Victor C. Vaughan. The total registration for 1910-11 was 260; graduates, 53. The sixty-second session begins Oct. 3, 1911, and ends June 27, 1912.

University of Michigan Homeopathic College.—Organized in 1875. The first class graduated in 1877. Although the work of the first two years taken in the same classes with the Department of Medicine and Surgery of the University of Michigan, nevertheless the entrance requirements are still kept at only a high-school education—a difference of two years of collegiate work! It is announced that one year of collegiate work will be required for admission in 1912 and thereafter. The Dean is Dr. W. B. Hinsdale. The total registration for 1910-11 was 92; graduates, 13. The next session begins Oct. 3, 1911, and ends June 27, 1912.

Detroit

Detroit College of Medicine, St. Antoine, Catherine and Mullett Streets and Gratiot Avenue.—Organized in 1885 by consolidation of Detroit Medical College, organized in 1868, and the Michigan College of Medicine, organized in 1880. The first class graduated in 1886. The faculty embraces 23 professors, 101 lecturers, instructors, etc., a total of 124. The course covers four years of eight months each. The Registrar is Dr. F. B. Walker. The total registration for 1910-11 was 163; graduates, 41. The twenty-seventh session begins Sept. 20, 1911, and ends May 23, 1912.

Detroit Homeopathic College, Lafayette Avenue and Third Street.—Organized in 1899. A class was graduated in 1900 and in each subsequent year. It has a faculty of 36. The course embraces four years of eight months each. Fees: From $75 to $95 per year. The Dean is Dr. D. A. Machlan. The total registration for 1910-11 was 21; graduates, 9. The thirteenth session begins Sept. 14, 1911, and ends May 19, 1912.

MINNESOTA

Minnesota, population 2,075,708, contains one medical college, the College of Medicine and Surgery of the University of Minnesota, situated in Minneapolis. Minneapolis and St. Paul are practically one city, and have a combined population of 516,162.

Minneapolis

University of Minnesota College of Medicine and Surgery.—Organized in 1883; reorganized in 1888 by absorption of St. Paul Medical College and Minnesota Hospital Medical College. The first class graduated in 1889. In 1908 the Minneapolis College of Physicians and Surgeons, organized in 1883, was merged. In 1909 the Homeopathic College of Medicine and Surgery was merged and provision made for elective chairs in didactic materia medica and therapeutics. Students electing these courses on graduation will receive the degree of Doctor of Medicine in Homeopathy. The faculty includes 67 professors and clinical professors and 81 associate professors, assistants, etc., a total of 148. The curriculum covers five years of nine months each, including a year's internship in a hospital. The entrance requirements are two years of university work which must include one year each of physics, general chemistry, qualitative analysis, zoology or botany, and German or French, all in addition to a four-year high school course, including Latin. Total fees for the first and second years are $150 each, and *for the third and fourth years* $100 each; microscopic rental, $1 to $4 per annum. The Dean is Dr. F. F. Wesbrook. The total registration for 1910-11 was 172, including 6 Hamline University students; *the graduates of* 1911 numbered 31, including 6 which were granted degrees by Hamline University. The twenty-fourth session begins Sept. 20, 1911, and ends June 14, 1912.

MISSISSIPPI

Mississippi, population 1,797,114, has two medical colleges. The Medical Department of the University of Mississippi giving only the first two years of the medical course, is located at Oxford, a city of 1,825 inhabitants. The Mississippi Medical College is located at Meridian, population 23,285.

Meridian

Mississippi Medical College, Fifth Street and Twenty-fourth Avenue.—Organized in 1906. The first class graduated in 1907. The faculty numbers 22. The course covers four years of seven months each. The Dean is Dr. T. A. Barber. The total registration for 1910-11 was 95; graduates, 19. The sixth session begins Oct. 2, 1911, and ends April 28, 1912.

Oxford

University of Mississippi Medical Department.—Organized in 1903. Gave *only the first two years of the* medical course until 1909, when a clinical department was organized at Vicksburg. Graduated one class in 1910, when the clinical years of the course were discontinued. *The course covers* four years of eight and a half months each. The faculty numbers 14. The Dean is Dr. W. S. Leathers. The total registration for 1910-11 was 50. The ninth session begins Sept. *21, 1911, and ends June 4, 1912.*

MISSOURI

Missouri, population 3,293,335, has nine medical colleges. St. Louis, population 687,029, contains five of these, viz., St. Louis College of Physicians and Surgeons, American Medical College, the School of Medicine of St. Louis University, Washington University Medical Department and Barnes Medical College. Kansas City, which with Kansas City, Kan., has a total population of 330,662, has two colleges, namely: the Kansas City Hahnemann Medical College and the Eclectic Medical University. Ensworth Medical College is located in St. Joseph, population 77,403. The Department of Medicine of the University of Missouri is at Columbia, a town of 9,662 people.

Columbia

University of Missouri School of Medicine.—Organized at St. Louis in 1845; was discontinued in 1859, but was reorganized at Columbia in 1872. Teaching of the clinical years was suspended in 1909. The faculty includes 10 professors, 7 assistant professors, lecturers, etc., a total of 17. The course covers two years of nine months each. The entrance requirements are two years of college work, including English, 5 hours; German, 5 hours; general zoology, 5 hours; physics, 5 hours; inorganic chemistry, 5 hours; Elective, 35 hours. Equivalent work in foreign language may be substituted for the English and German. Total fees are $70 each year. The Dean is Dr. C. M. Jackson. Total registration of students for 1910-11 was 34. The next session begins Sept. 21, 1911, and ends June 13, 1912.

Kansas City

Kansas City Hahnemann Medical College, 1020 East Tenth Street.—Organized in 1888 as the Kansas City Homeopathic Medical College. The first class graduated in 1899. In 1902 it united with the Hahnemann Medical College of the Kansas City University, taking the present title The Dean is Dr. William E. Cramer. Total registration for 1910-11 was 42; graduates, 7. The next session begins Sept. 7, 1911, and ends May 6, 1912.

Eclectic Medical University, 1423 Independence Avenue.—Organized at Kansas City, Mo., in 1898 with the present title. Moved to Kansas City, Kan., in 1907, and took the name of Western Eclectic College of Medicine and Surgery. *Returned to Kansas City*, Mo., in 1909 and resumed the present title. First class graduated in 1900. Fees are $100 each year. The Secretary is Dr. D. R. Alexander. The total registration for 1910-11 was 49; graduates, 12. The fourteenth session begins Sept. 4, 1911, and ends May 19, 1912. *Reported not in good standing by the Missouri State Board of Health.*

St. Joseph

The Ensworth Medical College, Seventh and Jule Streets.—Organized in 1876 as the St. Joseph Hospital Medical College. In 1882 it merged with the College of Physicians and Surgeons to form the St. Joseph Medical College In 1888 changed name to Ensworth Medical College. In 1905 merged with the Central Medical College, organized in 1894, to form the Ensworth-Central Medical College. In 1907 the present title was resumed. The faculty numbers 34. The course covers four years of thirty weeks each. The fees for the four years, respectively, are $90, $95, $75 and $95. The Secretary is Dr. T. E. Potter. Total registration for 1910-11 was 56; graduates, 9. The next session begins Oct. 1, 1911, and ends about May 31, 1912.

St. Louis

Washington University Medical School, 1806 Locust Street.—Organized in 1842 as the Medical Department of St. Louis University. In 1855 it was chartered as an independent institution under the name of St. Louis Medical College. The first class graduated in 1843. In 1891 it became the Washington University Medical School. In 1899 it absorbed the Missouri Medical College. The faculty comprises 39 professors, 54 lecturers and instructors, a total of 93. The course is four years of eight months each. The total fees for the four years are, respectively, $140.25, $142.75, $111.25 and $105.25. The Dean is Dr. George Dock. The total registration for 1910-11 was 123; graduates, 34. The next session begins Oct. 2, 1911, and ends June 8, 1912.

chool of Medicine, 1402 South Grand
by union of Marion-Sims Medical Col-
ld Beaumont Hospital Medical College,
ne the Medical Department of St. Louis
faculty is composed of 37 professors, 75 lecturers and assistants, a total of 112. The curriculum covers four years of eight months each. The total fees are $110 each year. The Dean is Dr. E. P. Lyon. The total registration for 1910-11 was 274; graduates, 50. The next session begins Oct. 2, 1911, and ends May 29, 1912.

St. Louis College of Physicians and Surgeons, Jefferson *Avenue and Gamble Street.—Organized in 1869. Classes graduated* in 1870 and in each subsequent year until 1873, when it suspended. It was reorganized in 1879. Classes graduated in 1880 and subsequent years. The Dean is Dr. Waldo Briggs, 2600 Gamble Street. Total registration for 1910-11 was 52; graduates, 22.

Barnes Medical College, Garrison and Lawton Avenues.—Organized in 1892. Classes graduated in 1893 and in all subsequent years except 1899. The faculty consists of 40 professors and 8 lecturers and assistants, a total of 48. The course covers four years of eight months each. The total fees are $100 each year. The Dean is Dr. A. R. Kieffer. Total registration for 1910-11 was 176; graduates, 52. The next session begins *Sept.* 14, 1911, and ends about May 13, 1912.

American Medical College, 407 South Jefferson Avenue.—Organized in 1873 as an Eclectic College. Eclecticism dropped in 1910. Two classes were graduated each year from 1874 to 1883, inclusive. Since then one class has graduated each year. The course covers four years of nine months each. The fees are $100 each year. The Dean is Dr. James Moores Ball. The total registration for 1910-11 was 46; graduates, 12. The next session begins Sept. 11, 1911, and ends June 2, 1912.

NEBRASKA

Nebraska, population 1,192,214, has three medical colleges: The University of Nebraska College of Medicine and the John A. Creighton Medical College at Omaha, population 124,096, and the Lincoln Medical College at Lincoln, population 43,973.

Lincoln and Omaha

College of Medicine University of Nebraska, Eleventh and R Streets, *Lincoln*, and Twelfth and Pacific Streets, Omaha.—Organized in 1881 as the Omaha Medical College. The first class graduated in 1882. It became the Medical Department of Omaha University in 1891. In 1902 it affiliated with the University of Nebraska, with the present title. Two years of collegiate work are required for admission. The first two years are given at Lincoln: the last two at Omaha. The faculty is composed of 29 professors and 38 lecturers and instructors, total 67. The fees are approximately $100 per annum. Total registration for 1910-11 was 72; graduates, 10. The next session begins Sept. 12, 1911, and ends May 31, 1912.

Lincoln

Lincoln Medical College. Eclectic. Corner 13th and P Streets. It is the Medical Department of Cotner University.—Organized in 1890. The first class graduated in 1891. The Secretary is Dr. R. H. Spradling. The total registration for 1910-11 was 42; graduates, 9.

Omaha

John A. Creighton Medical College, Fourteenth and Davenport Streets. It is the Medical Department of Creighton University.—Organized in 1892. The first class graduated in 1895. It *has a faculty of 30 professors and 18 associates, lecturers and assistants*, a total of 48. The course of study embraces four years of eight months each. The total fees for the four years, respectively, are $105, $100, $100 and $105. The Dean is Dr. D. C. Bryant, McCague Building. Total number of students registered in 1910-11 was 188; graduates, 43. The twentieth session begins Sept. 4, 1911, and ends April 27, 1912.

NEW HAMPSHIRE

New Hampshire, population 443,140, has one medical college, located at Hanover, population 1,884.

Hanover

Dartmouth Medical School.—Organized as New Hampshire Medical Institute in 1797. The first class graduated in 1798. It is the Medical Department of Dartmouth College. The faculty is made up of 23 professors and 6 instructors, a total of 29. Two years of collegiate work are required for admission. The course covers four years of eight months each. The fees are $125 each year. The Dean is Dr. John M. Gile. The total registration for 1910-11 was 42; graduates, 11. The work of the first and second years begins with that of the academic department Sept. 21, 1911, and ends June 25, 1912; for the advanced classes the course begins Aug. 1, 1911, and ends April 18, 1912.

NEW YORK

New York State, population 9,113,614, has eleven medical colleges. Eight of these, College of Physicians and Surgeons (Columbia University), Long Island College Hospital, New York Homeopathic Medical College and Hospital, New York Medical College and Hospital for Women, Eclectic Medical College of the City of New York, Cornell University Medical College, the University and Bellevue Hospital Medical College, and Fordham University School of Medicine, are located in New York City, population 4,766,883. Albany Medical College is located in Albany, a city of 100,253 people. The University of Buffalo Medical Department is situated in Buffalo, population 423,715. The College of Medicine, Syracuse University, is in Syracuse, a city of 137,249 inhabitants.

Albany

Albany Medical College, Lancaster and Jay Streets.—Organized in 1838. The first class graduated in 1839. It became the Medical Department of Union University in 1873. The faculty is composed of 27 professors and 72 lecturers, assistants, etc., a total of 99. The curriculum covers four years of eight months each. Fees: First year, $130; second year, $145; third year, $120, and fourth year, $130. The Registrar is Dr. Willis G. Tucker. The total registration for 1910-11 was 208; graduates, 42. The eighty-first session begins Sept. 19, 1911, and ends May 14, 1912.

Buffalo

University of Buffalo Medical Department, High Street, near Main.—Organized in 1846. The first [illegible] 347. It absorbed the Medical Department of [illegible] n 1898. The faculty is composed of 36 profess [illegible] assistants, etc., a total of 82. The course covers four years of eight months each. The total fees for the four years, respectively, are $185, $180, $140 and $140. The Dean is Dr. Matthew D. Mann, 37 Allen Street. Total registration for 1910-11 was 223; graduates, 41. The sixty-sixth session begins Sept. 25, 1911, and ends May 31, 1912.

New York

Columbia University College of Physicians and Surgeons, 437 West Fifty-ninth Street.—Organized in 1807 by the regents of the University of the State of New York as their medical department. The first class graduated in 1811. Affiliated with Columbia College in 1814 and was permanently connected in 1860, when it became the Medical Department of Columbia College. That institution became Columbia University in 1891. The faculty is composed of 55 professors and 121 instructors, demonstrators, etc., a total of 176. Two years of collegiate work, including courses in physics, chemistry and biology are required for admission. The work covers four years of eight months each. The Dean is Dr. Samuel W. Lambert. The total fees for the first year are $255; for the second and third, $250, and $275 for the fourth year. Total registration for 1910-11 was 328; graduates, 70. The 104th session begins Sept. 27, 1911, and ends June 5, 1912.

Cornell University Medical College, First Avenue and Twenty-Eighth Street, New York City, and Ithaca.—Organized in 1898. The first class was graduated in 1899. The work of the first year may be taken either in Ithaca or New York. The faculty is composed of 53 professors and 86 assistants, lecturers, instructors, etc., a total of 139. All candidates for admission must be graduates of approved colleges or scientific schools and in addition must have such knowledge of physics, inorganic chemistry and biology as may be obtained in college by a year's course in these subjects when accompanied by laboratory work. Fees: First year, $190; second and third, $185 each, and $200 for the fourth year. The Dean is Dr. William M. Polk. Total registration for 1910-11 was 116; graduates, 55. The fourteenth session begins Sept. 27, 1911, and ends June 12, 1912.

Eclectic Medical College of the City of New York, 239 East Fourteenth Street.—Organized in 1865. The first class graduated in 1867. The faculty consists of 19 professors and 24 lecturers, assistants, etc., a total of 43. The course covers four years of eight months each. The Dean is Dr. Samuel A. Hardy. Total registration for 1910-11 was 77; graduates, 10. The next session begins Sept. 14, 1911, and ends May 1, 1912.

Fordham University School of Medicine, Third and Pelham Avenues.—Organized in 1905. First class graduated in 1909. The faculty consists of 35 professors and 34 lecturers and assistants, a total of 69. The course of instruction covers four years of nine months each. Fees, $200 each year. A year's work in a recognized college of liberal arts is required for admission. The Dean is Dr. James J. Walsh. The total registration for 1910-11 was 94; graduates, 17. The seventh session begins Sept. 20, 1911, and ends June 14, 1912.

Long Island College Hospital, Henry Street, near Atlantic Avenue, Brooklyn.—Organized in 1858. The first class graduated in 1860. It has a faculty of 9 professors and 86 assistants, insructors, etc., a total of 95. The course covers four years of eight months each. Fees: First year, $205; second year, $200; third, $180, and $200 for the fourth year. The Secretary is Dr. Joseph H. Raymond. Total registration, 1910-11, was 407; graduates, 73. The fifty-fourth session begins Sept. 28, 1911, and ends June 3, 1912.

New York Homeopathic Medical Col [illegible] ern Boulevard, between Sixty-third and [illegible] ganized in 1858. Incorporated in 1860 as [illegible] College for the State of New York. The [illegible] in 1869. The first class graduated in 1861. The faculty consists of 32 professors and 28 assistants, lecturers, etc., a total of 60. The Dean is Dr. Royal S. Copeland. Total registration for 1910-11 was 210; graduates, 14. The next session begins Oct. 5, 1911, and ends June 1, 1912.

New York Medical College and Hospital for Women, 17-19 West One Hundred and First Street.—Organized in 1863. The first class graduated in 1864. The faculty consists of 30 professors and 20 lecturers and assistants, a total of 50. The course covers four years of thirty weeks each. The fees for each of the four years, respectively, are $155, $150, $135 and $155. The Dean is Dr. Helen Cooley Palmer. The total registration for 1910-11 was 24; graduates, 4. Names of matriculants not printed in the annual announcement. The forty-ninth session begins Oct. 2, 1911, and ends May 24, 1912

University and Bellevue Hospital Medical College, First Avenue and Twenty-sixth Street.—Organized in 1898 by the union of the New York University Medical College, organized in 1841, and the Bellevue Hospital Medical College, organized in 1861. It is the Medical Department of New York University. The faculty is composed of 35 professors and 139 instructors, etc., in all 174. The course covers four years of eight months each. The fees are $200 per year. The Dean is Dr. Egbert Le Fevre. Total registration for 1910-11 was 511; graduates, 68. The next session begins Sept. 27, 1911, and ends June 1, 1912.

Syracuse

Syracuse University College of Medicine, 307-311 Orange Street.—Organized in 1872 as the College of Physicians and Surgeons of Syracuse University. The present title was assumed in 1875. In 1872 Geneva Medical College was merged with it. The first class was graduated in 1873. The faculty is composed of 15 professors and 45 assistant professors, lecturers and instructors, in all 60. The course covers four years of eight months each. The completion of two years in an accredited college of liberal arts is required for admission. The total fees for each of the four years, respectively, are $181, $191, $151 and $166. The Dean is Dr. John L. Heffron. The total registration for 1910-11 was 109; graduates, 29. The fortieth session begins Oct. 3, 1911, and ends June 12, 1912.

NORTH CAROLINA

North Carolina, population 2,206,287, has four medical schools, two of which give only the first two years of the medical course. The Medical Department of the University of North Carolina is located at Chapel Hill, population 1,200. The Leonard School of Medicine is at Raleigh, population 19,218. The North Carolina College is at Charlotte, population 34,014. Wake Forest School of Medicine is at Wake Forest, population 823.

Chapel Hill

University of North Carolina Medical Department.—Organized in 1890. Until 1902 this school gave only the work of the first two years, when the course was extended to four years by the establishment of a department at Raleigh. The first class graduated in 1903. The eighteenth session begins Oct. 3, 1911, and ends May 27, 1912.

Wisconsin College of Physicians and Surgeons, Fourth Street and Reservoir Avenue.—Organized in 1893. The first class graduated in 1894. In 1898 it became the medical department of Carroll College. It has a faculty of 20 professors and 34 lecturers, instructors, etc., a total of 54. The curriculum includes four years of eight months each. Total fees each year for the four years, respectively, are $145, $135, $130 and $145. The Dean is Dr. Thomas C. Phillips. The total registration for 1910-11 was 55; graduates, 16. The twentieth session begins Oct. 2, 1911, and ends May 24, 1912.

CANADA

Manitoba

Manitoba Medical College, Winnipeg.—It is the Medical Faculty of the University of Manitoba. Organized in 1883, first class graduated in 1886 and a class graduated each subsequent year. The faculty numbers 50. The fees are $155 for the first year and $150 for each subsequent year. The entire course covers five years. The Dean is Dr. H. H. Chown, 263 Broadway, Winnipeg. Total registration for 1910-11 was 137; graduates, 18. The next session begins Oct. 1, 1911, and ends May 1, 1912.

Nova Scotia

Dalhousie Medical College, Medical Faculty of Dalhousie University, Halifax.—Organized 1867 as Halifax School of Medicine, united same year with Dalhousie University, separately incorporated 1876, affiliated with Dalhousie University 1885, first class graduated 1872 and a class graduated each subsequent year except 1873 and 1886. The Medical Faculty of Dalhousie University is the Examining Board for Nova Scotia and teaches only the premedical branches; Halifax Medical College taught the medical courses, but the Medical Faculty conducted the examinations and granted the degrees. Entire control secured by Dalhousie University in 1911. The course covers four years. The Dean is Dr. George L. Sinclair; the Secretary is Dr. A. W. H. Lindsay. The total registration for 1910-11 was 71; graduates, 16. The next session begins Aug. 31, 1911, and ends April 28, 1912.

Ontario

University of *Toronto Faculty of Medicine, Toronto.*—Organized 1843 as the Medical Faculty of King's College. Abolished in 1853. Re-established in 1887. The course of study covers five years of eight months each. In 1903 it absorbed Trinity Medical College. The Secretary is Dr. A. Primrose. The total registration for 1910-11 was 510; graduates, 143. The next session begins Sept. 27, 1911, and ends May 18, 1912.

Medical Faculty of Queen's University, Kingston.—Organized 1854, first class graduated in 1855, and a class graduated each subsequent year. The faculty was originally a department of the University, but a separation took place in 1866, when the school was conducted under the charter of the Royal College of Physicians and Surgeons at Kingston. In 1892 the school again became an integral part Queen's University. The fees amount to $105 each year; fee for M.D., C.M. degrees, $30. The course covers five years of seven months each. The total registration in 1910-11 was 232; graduates, 46. The Dean is Dr. A. R. B. Williamson. The next session begins Sept. 13, 1911, and ends April 24, 1912.

Medical Department of Western University, London.—Organized in 1881, first class graduated in 1883 and a class graduated each year *subsequently. The faculty numbers 26. The course* is five years of seven and a half months each. The Registrar is Dr. W. E. Waugh. Total registration for 1910-11 was 129; graduates, 26. The *next session begins* Sept. 12, 1911, and ends April 30, 1912.

Quebec

Medical Faculty of McGill University.—Founded 1824 as Montreal *Medical Institution; became the Medical Faculty* of McGill University in 1829; first class graduated under the university auspices in 1833. No session between 1836-39 owing to political troubles. In 1905 it absorbed the Faculty of Medicine of the University of Bishop College. The course extends over five years of eight months each. The faculty numbers 100. The total fees for each of the five years, respectively, are $160, $160, $148, $154 and $184. The total registration for 1910-11 was 308; graduates, 31. The Registrar is Dr. John W. Scane. The next session begins Oct. 2, 1911, and ends June 12, 1912.

Laval University Medical Department, Quebec.—The Quebec School of Medicine, organized in 1848, became in 1852 Medical Department of Laval University; first class graduated in 1855, and a class graduated each subsequent year. The course extends over five years. The Dean is Dr. Michael Joseph Ahern, Quebec. Total registration 1910-11 was 84; graduates, 19. The next session begins Sept. 12, 1911, and ends June 20, 1912.

Laval University, Medical Department, Montreal.—Organized in 1878. First class graduated in 1879. The course extends over five years. The Dean is Dr. E. P. Lachapelle. The total registration for 1910-11 was 195; graduates, 51. The next session begins Oct. 2, 1911, and ends June 20, 1912.

MEDICAL COLLEGES OF THE WORLD.

Nation.	Colleges.	Nation.	Colleges.

Total medical colleges in all foreign countries............200
Total in the United States alone..............................120

Counting also the 20 sectarian schools, the graduates of which treat diseases, gives the United States a total of 140.

STANDARDS OF THE COUNCIL ON MEDICAL EDUCATION OF THE AMERICAN MEDICAL ASSOCIATION

These standards were prepared by the Council on Medical Education acting under the direction of the House of Delegates of the American Medical Association.

Standard Now Recommended

The standard now recommended prerequisite to the practice of medicine is as follows:

(A) Preliminary education sufficient to enable the candidate to enter our recognized universities, such qualifications to be passed on by the state authorities. (B) A premedical course of one or two years devoted to the sciences of physics, chemistry and biology and to modern languages. (C) Four years in pure medical work, the first two of which should be largely spent in laboratories of anatomy, physiology, pathology, pharmacology, etc., and the last two in close contact with patients in dispensaries and hospitals in the study of medicine, surgery, obstetrics, and the specialities. (D) A final year as an interne in a hospital or dispensary should then complete the medical course.

Standard High School Course

SCHEDULE OF SUBJECTS OFFERED IN ACADEMIC AND SECONDARY SCHOOLS, CREDITS IN WHICH ARE ACCEPTABLE FOR ENTRANCE TO MEDICAL COLLEGES

Based on the requirements of the College Entrance Examination Board.

Total	34	8	26

A *unit* is the credit value of 36 weeks' work of 5 recitation periods per week, each recitation period to be of not less than 40 minutes.

Required Branches: Of the 14 units of high school work it is suggested that the subjects in capitals aggregating 8 units should be required. Other work to the amount of at least 6 units may be made up from any of the other subjects of the above schedule.

* Two units of Greek may be substituted for the two required units of Latin.

** A reading knowledge of German, French or other modern language is recommended in the high school courses of students contemplating the study of medicine without higher preliminary qualifications.

† It should be understood that each science course must include laboratory work.

Under such a scheme the majority of men would begin the study of medicine between 18 and 19 years of age, and would graduate from the hospital internship at from 24 to 25. A college education is recognized as a desirable preparation for a limited number of men, but it is thought that it is not and never will be desirable to make such college education a minimum requirement to the study of medicine, as it would make the age of graduation from 27 to 28 years, which is regarded as too old a period at which the young medical man should begin his life's work.

An Acceptable Medical College

The following outline of the essentials of an acceptable medical college was issued by the Council on Medical Education of the American Medical Association for its suggestive value in the rapid development in progress among the medical colleges in the United States:

1. A strict enforcement of all standards and requirements, the college itself to be held responsible for any instances where they are not enforced.

2. A requirement for admission of at least a four-year high school education superimposed on eight years of grammar school work as defined by the College Entrance Examination Board and required by the Carnegie Foundation for the Advancement of Teaching (see schedule, opposite column).

3. As soon as conditions warrant, the minimum requirement for admission should be enlarged to include at least one year's college work in physics, chemistry and biology and a reading knowledge of at least one modern language, preferably German or French.

4. A requirement that students be in actual attendance in the college within the first week of each annual session and thereafter.

5. That actual attendance at classes be insisted on except for good cause, such as for sickness, and that no credit be given under any circumstances for less than 80 per cent. of attendance on each course.

6. That advanced standing be granted only to students of other acceptable colleges and that in granting advanced standing there shall be no discrimination against the college's full-course student.

7. Careful and intelligent supervision of the entire school by a dean or other executive officer who holds, and has sufficient authority to carry out, fair ideals of medical education as interpreted by modern demands.

8. A good system of records showing conveniently the credentials, attendance, grades and accounts of the students.

9. A fully graded course covering four years of at least 30 weeks each, exclusive of holidays, and at least 30 hours per week of actual work; this course should be clearly set forth in a carefully prepared and printed schedule of lectures and classes.

10. Two years of work consisting largely of laboratory work in thoroughly equipped laboratories in anatomy, histology, embryology, physiology, chemistry (inorganic, organic and physiologic), bacteriology, pathology, pharmacology, therapeutics and clinical diagnosis.

11. Two years of clinical work largely in hospitals and dispensaries, with thorough courses in internal medicine (including physical diagnosis, pediatrics, nervous and mental diseases), surgery (including surgical anatomy and operative surgery on the cadaver), obstetrics, gynecology, laryngology, rhinology, ophthalmology, otology, dermatology, hygiene and medical jurisprudence.

12. At least six expert, thoroughly trained instructors in the laboratory branches, salaried so they may devote their entire time to instruction and to that research without which they cannot well keep up with the rapid progress being made in their subjects. These instructors should rank sufficiently high to have some voice in the conduct of the college. There should also be a sufficient number of assistants in each department to look after the less important details.

13. The medical teaching should be of at least the same degree of excellence as obtains in our recognized liberal arts colleges and technical schools.

14. The members of the faculty, with a few allowable exceptions, should be graduates of institutions recognized as medical colleges and should have had a training in all departments of medicine. They should be appointed because of their ability as teachers and not because they happen to be on the attending staff of some hospital or for other like reasons.

15. The college should own or entirely control a hospital in order that students may come into close and extended contact with patients under the supervision of the attending staff. The hospital should have a sufficiently large number of patients to permit the student to see and study the common variety of surgical and medical cases as well as a fair number in each of the so-called specialties.

16. The college should have easily accessible hospital facilities of not less than 200 patients which can be utilized for clinical teaching (for senior classes of 100 students or less), these patients to represent in fair proportion all departments of medicine.

17. The college should have additional hospital facilities for children's diseases, contagious diseases and nervous and mental diseases.

18. Facilities for at least five maternity cases for each senior student, who should have actual charge of these cases under the supervision of the attending physician.

19. Facilities for at least 30 autopsies during each college session (for senior classes of 100 students or less).

20. A dispensary, or out-patient department, under the control of the college, the attendance to be a daily average of 60 cases (for senior classes of 100 students or less), the patients to be carefully classified, good histories and records of the patients to be kept and the material to be well used.

21. The college should have a working medical library to include the more modern text and reference books and 10 or more leading medical periodicals; the library room to be easily accessible to students during all or the greater part of the day; to have suitable tables and chairs and to have an attendant in charge.

22. A working medical museum having its various anatomic, embryologic, pathologic and other specimens carefully prepared, labeled and indexed so that any specimen may be easily found and employed for teaching purposes.

23. A supply of such useful auxiliary apparatus as a stereopticon, a reflectoscope, carefully prepared charts, embryologic or other models, manikins, dummies for use in bandaging, a Roentgen ray or other apparatus now so generally used in medical teaching.

24. The colleges should show evidences of reasonably modern methods in all departments and evidences that the equipment and facilities are being intelligently used in the training of medical students.

25. A clear statement of the college's requirements for admission, tuition, time of attendance on the classes, sessions and graduation should be clearly set forth, together with complete lists of its matriculants and latest graduating class in regular annual catalogues or announcements.

Definitions of a Medical College* and a Medical School†

"An institution to be ranked as a medical college must have at least six (6) professors giving their entire time to medical work, a graded course of four full years of college grade in medicine, and must require for admission not less than the usual four years of academic or high-school preparation, or its equivalent, in addition to the preacademic or grammar school studies."

By a medical school as differentiated from a medical college is meant a part of a university requiring for admission the equivalent of two years of collegiate work and which offers instruction of not less than two years' duration, leading to the degree of Doctor of Medicine.

---

* This definition of a college is based on that given in the revised ordinances of the State of New York and which was adopted by the Carnegie Foundation for the Advancement of Teaching as their standard.

† Based on the definition of the term "school" adopted in 1909 by the Association of American Universities.

COLLEGES LISTED AS ACCEPTABLE (CLASS A)

By the Council on Medical Education of the American Medical Association

1. Giving a complete four-year course:

ALABAMA
University of Alabama Medical Department.

CALIFORNIA
Leland Stanford Junior University Medical Department (Cooper Medical College).
University of California Medical Department, San Francisco-Los Angeles.

COLORADO
University of Colorado, School of Medicine.

CONNECTICUT
Yale Medical School.

DISTRICT OF COLUMBIA
George Washington University, Department of Medicine.
Georgetown University, School of Medicine.

ILLINOIS
Northwestern University Medical School.
Rush Medical College, University of Chicago.
College of Physicians and Surgeons, Chicago.
Hahnemann Medical College and Hospital, Chicago.

INDIANA
Indiana University School of Medicine.

IOWA
State University of Iowa, College of Medicine.
State University of Iowa, Homeopathic College.
Drake University, College of Medicine.

KANSAS
University of Kansas, School of Medicine.

KENTUCKY
University of Louisville, Medical Department.

LOUISIANA
Tulane University of Louisiana, Medical Department.

MAINE
Medical School of Maine.

MARYLAND
Johns Hopkins University, Medical Department.
University of Maryland, School of Medicine.
College of Physicians and Surgeons, Baltimore.
Baltimore Medical College.

MASSACHUSETTS
Boston [illegible] Medicine.
Harvard [illegible]
Tufts [illegible]

MICHIGAN
University of Michigan, Department of Medicine and Surgery.
University of Michigan, Homeopathic College.
Detroit College of Medicine.

MINNESOTA
University of Minnesota, College of Medicine and Surgery.

MISSOURI
St. Louis University, School of Medicine.
Washington University Medical Department.
University Medical College, Kansas City.

NEBRASKA
Creighton Medical College.
University of Nebraska, College of Medicine.

NEW HAMPSHIRE
Dartmouth Medical School.

NEW YORK
Albany Medical College.
Columbia University, College of Physicians and Surgeons.
Cornell University Medical College.
[illegible] hool of Medicine.
[illegible] spital.
[illegible] Medical College and Hospital.
Syracuse University, Medical Department.
University and Bellevue Hospital Medical College.
University of Buffalo, Medical Department.

OHIO
Ohio-Miami Medical College, Medical Department, University of Cincinnati.
Starling-Ohio Medical College.
Western Reserve University, Medical Department.

OREGON
University of Oregon, Medical Department.

PENNSYLVANIA
[illegible] and Hospital, Philadelphia.
[illegible] of Philadelphia.
[illegible] Medical Department.
[illegible] Pennsylvania.
[illegible] dical Department.

TENNESSE
Vanderbilt University, Medical Department.

TEXAS
University of Texas, Medical Department.

VERMONT
University of Vermont, College of Medicine.

VIRGINIA
Medical College of Virginia.
University College of Medicine.
University of Virginia, Department of Medicine.

2. Giving a two-year course acceptably:

MISSISSIPPI
University of Mississippi, Medical Department.

MISSOURI
University of Missouri, Medical Department.

NORTH CAROLINA
University of North Carolina College of Medicine
Wake Forest College, Medical School.

NORTH DAKOTA
University of North Dakota, College of Medicine.

OKLAHOMA
University of Oklahoma School of Medicine.
SOUTH DAKOTA
University of South Dakota, College of Medicine.
UTAH
University of Utah, Department of Medicine.
WEST VIRGINIA
West Virginia University, Department of Medicine.
WISCONSIN
University of Wisconsin, College of Medicine.

3. Medical Schools for the Colored Race:
Howard University, Medical Department, Washington, D. C.
Meharry Medical College, Nashville, Tenn.

Colleges and States Having Higher Requirements

The twenty-eight medical schools which are now requiring as a minimum for entrance two or more years of work in a college of liberal arts in addition to a four-year high-school education are as follows:

College	Began
Johns Hopkins University, Medical Department	1893
Harvard Medical School	1900
Western Reserve University, Medical Department	1901
University of Chicago, Rush Medical College	1904
University of California, Medical Department	1905
University of Minnesota, College of Medicine and Surgery	1907
University of North Dakota, College of Medicine	1907
University of Wisconsin, College of Medicine	1907
Cornell University Medical College	1908
Wake Forest College, School of Medicine	1908
Leland Stanford Junior University, Department of Medicine	1909
Yale Medical School	1909
University of Kansas, School of Medicine	1909
University of Michigan, College of Medicine	1909
University of Nebraska, College of Medicine	1909
University of South Dakota, College of Medicine	1909
University of Colorado, School of Medicine	1910
Indiana University School of Medicine*	1910
State University of Iowa, College of Medicine*	1910
State University of Iowa, College of Homeopathic Medicine	1910
Drake University College of Medicine	1910
University of Missouri, Department of Medicine†	1910
Dartmouth Medical School	1910
Columbia University College of Physicians and Surgeons	1910
Syracuse University College of Medicine*	1910
University of Pennsylvania, Medical Department*	1910
University of Utah, Medical Department*	1910
Northwestern University Medical School‡	1911

* One year required for the session of 1909-10.
† One year has been required since 1906.
‡ One year required since the session of 1908-09.

The thirteen following colleges require in addition to a four-year high-school course one year of work in a college of liberal arts.

College	In Force
Howard University School of Medicine	1910
Kansas Medical College	1910
Tulane University, Medical Department	1910
St. Louis University School of Medicine	1910
University Medical College, Kansas City	1910
Washington University, Medical Department*	1910
University of North Carolina School of Medicine	1910
Ohio-Miami Medical College, University of Cincinnati	1910
University of Oregon, Medical Department	1910
University of Texas, Medical Department	1910
University of Virginia, Department of Medicine	1910
Fordham University School of Medicine	1911
University of Pittsburgh, Medical Department	1911

* Will require two years in 1912 and thereafter.

Six other colleges have stated in printed announcements that one year of collegiate work in addition to a four year high-school education will be required for admission beginning in 1912. These are:

Georgetown University School of Medicine.
Boston University School of Medicine.
Medical School of Maine.
University of Michigan, Homeopathic College.
University and Bellevue Hospital Medical College.
University of Vermont, College of Medicine.

From the fact that forty-seven medical colleges have adopted higher entrance requirements it is interesting to note that nine state examining boards have also adopted preliminary requirements in advance of a four-year high-school education. These are as follows:

State Examining Board of	No. of Years Required.	Affects Students Matriculating.	Affects All Applicants.
North Dakota	2	1907-08	1911
South Dakota	1	1907-08	1911
Iowa	2	1907-08	1911
Minnesota	2	1908-09	1912
Colorado	1	1908-09	1912
Colorado	2	1910-11	1914
Connecticut	1	1910-11	1914
Kansas	1	1910-11	1914
Indiana	1	1909-10	1913
Indiana	2	1910-11	1914
Utah	1	1910-11	1914

There are several other states which are contemplating similar increases in their requirements in the near future.

THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES

The requirements for admission to and graduation from colleges holding membership in force prior to April 10, 1905, were as follows:

SECTION 1.—Each college holding membership in this Association shall require of each student, before admission to its course of study, an examination, the minimum of which shall be as follows:

1. In English, a composition on some subject of general interest. This composition must be written by the student at the time of the examination, and should contain at least 200 words. It should be criticized in relation to thought, construction, punctuation, spelling and handwriting.

2. In Arithmetic, such questions as will show a thorough knowledge of common and decimal fractions, compound numbers, and ratio and proportion.

3. In Algebra, such questions as will bring out the student's knowledge of the fundamental operations, factoring, and simple quadratic equations.

4. In Physics, such questions as will discover the student's understanding of the elements of mechanics, hydrostatics, hydraulics, optics and acoustics.

5. In Latin, an examination on such elementary work as the student may offer, showing a familiarity usually attained by one year of study; for example, the reading of the first fifteen chapters of Cæsar's Commentaries, and the translation into Latin of easy English sentences involving the same vocabulary.

SEC. 2.—In place of this examination, or any part of it, colleges, members of this Association, are at liberty to recognize the official certificates of reputable literary and scientific colleges, academies, high schools, and normal schools, and also the medical student's certificate issued by any state examining board covering the work of the foregoing entrance examination.

SEC. 3.—Colleges, members of this Association, may allow students who fail in one or more branches in this entrance examination the privilege of entering the first-year course, but such students shall not be allowed to begin the second course until the entrance requirements are satisfied.

SEC. 4.—Colleges, members of this Association, are free to honor official credentials issued by medical colleges of equal requirements, except in the branches of study embraced in the last year of their own curriculum.

SEC. 5.—Candidates for the degree of Doctor of Medicine in the year 1899 and thereafter shall have attended at least four courses of medical instruction, each course of at least six months' duration, no two courses of which shall have been in the same calendar year.

SEC. 6.—Colleges, members of this Association, are free to give to students who have met the entrance requirements of the Association additional credit for time on the four years' course as follows: (a) To students having the A.B., B.S., or equivalent degree from reputable literary colleges, one year of time; (b) To graduates and students of colleges, of medicine, as many years as they attended hey have met the previous requirements c hat they pass an examination in materia (3) To graduates of reputable colleges o d veterinary medicine, one year of time.

On April 10, 1905, a new constitution was adopted, which is here given with such amendments as have been made since that time (except where the entire section is changed parts affected by later amendments are inclosed in brackets [] and amendments are printed in italics):

ARTICLE III.

SECTION 1.—Every college holding membership in this Association shall demand of each student, under the condition hereinafter stated, as a minimum requirement for admission to the medical course:

(On and after Jan. 1, 1912, the above paragraph is no longer effective, the following substitute having been adopted Feb. 28, 1911:

SECTION 1.—Every college holding membership in this Association shall, on and after Jan. 1, 1912, require for matriculation a completed or unconditioned medical student's certificate, to be granted by a state medical examining and licensing board, or a board empowered by statute to grant such certificates, or a certificate of entrance to the academic department of any state university, or a certificate of entrance to an accredited university or college, providing that said certificate is granted on no less than the following requirements:

(*a*) A bachelor's degree from an accredited college or university.

(*b*) A diploma from an accredited high school, normal school or academy requiring for admission evidence of the completion of an eight-year course in primary and intermediate grades, and for graduation not less than four years of study embracing not less than two years (4 points) [of foreign language, of which one must be Latin], two years (4 points) of mathematics, two years (4 points) of English, one year (2 points) of history, two years (4 points) of laboratory science, and six years (12 points) of further credit in language, literature, history or science.

Amended May 6, 1907, as follows:

(*b*) A diploma from an accredited high school . . . embracing not less than two years (4 points) *of Latin*, two years (4 points) of mathematics, two years (4 points) of English, one year (2 points) of history, [two years (4 points) of laboratory science], and six years (12 points) of further credit in language, literature, history or science.

(*Continued on page 645*)

H., Homeopathic; E., *Eclectic*; Ph.M., Physiomedical. * Night schools. † Gives only two years of the medical course.

REFERENCES TO TABLE I.

(a) The *College of Physicians* and Surgeons of Little Rock has united with the University of Arkansas Medical Department and the consolidated school will be entirely *controlled* and financed hereafter by the *University of* Arkansas.

(b) Cooper Medical College will continue until the students enrolled at the time of its merger with the Leland Stanford University in 1908 have been *graduated*. It will then cease to exist and the Leland Stanford will teach all four years of the medical course.

(c) Formerly the College of *Physicians and* Surgeons. The school is *now* an integral part and entirely under the control of the University of Illinois.

(d) The College of Medicine and Surgery, the last *of* the physiomedical *colleges, has* been absorbed by the Chicago College of Medicine and Surgery.

(e) This college, which held its sessions at night, has *been* discontinued.

(f) The population figures given are for both Kansas City, Kansas, and Kansas City, Missouri.

(g) Flint Medical College has been temporarily suspended.

(h) The College of Physicians and Surgeons of Boston is not included in the list of medical colleges *recognized by* the Massachusetts *Medical Society.*

(i) The population figures given are for the adjoining cities of Minneapolis and St. Paul.

(j) This is the *last medical class* which will be graduated by *the Hamline* University Medical Department. Under the agreement whereby this school was merged with the University of Minnesota, College of Medicine *and Surgery*, the Hamline University *was to* grant degrees for all students enrolled at the time of the merger who were not eligible for the degree from the University of Minnesota.

(k) *See note (i).*

(l) This University Medical College has been permanently suspended.

(m) The *Eclectic* Medical University is said to be not in good standing with the Missouri State Board of Health.

(n) Last year an offshoot of the Lincoln Medical College was organized under the *name of* the Nebraska Medical College. They have been reunited, however, and will continue as the Medical Department of Cotner University.

(o) The *College of* Physicians and Surgeons of Cleveland has been merged into the Western Reserve University Medical Department but by the terms of the agreement will *continue* to grant degrees until *all the students* enrolled at the time of the merger, who were not eligible to receive the degree from Western Reserve, have been graduated.

(p) The union between the Medical Departments of the University *of* Nashville and the University of Tennessee has been dissolved, the former has ceased to exist and the latter has been moved to Memphis where it will occupy the building of the College *of* Physicians and Surgeons, with which it has been consolidated.

(p) The Medical Department of *Fort Worth* University has taken the title of *Fort Worth* School of Medicine and by affiliation has become the Medical Department of the Texas Christian University. Neither institution assumes any liability *for* the conduct or the expenses of the other.

(r) This college was closed by the Regents of West Virginia University at the end of the session of 1910-11.

(Continued from page 641)

Amended March 17, 1908, as follows:

(b) A diploma from an accredited high school . . . embracing not less than two years (4 points) [of Latin], two years (4 points) of mathematics, two years (4 points) of English, one year (2 points) of history, *one year (2 points) of physics*, and six years (12 points) of further credit in language, literature, history or science.

Amended March 21, 1910, as follows:

(b) A diploma from an accredited high school . . . embracing two years (4 points) of Latin, *or four years (8 points) of either high school French or German or its full equivalent, provided a satisfactory examination is passed in the elements of Latin grammar;* two years (4 points) of mathematics, two years (4 points) of English, one year (2 points) of history, one year (2 points) of physics, and six years (12 points) of further credit in language, literature, history or science.

(c) An examination in the following branches: A. Required, 18 points: Mathematics, 4 points; English, 4 points; History, 2 points; [Language (2 must be Latin), 4 points]; Science (taken from physics, chemistry, botany, zoology), 4 points.

B. Optional (to 12 points): English, 2 points; History, 6 points; Language, 6 points; Manual Training, 2 points; Mechanical Drawing, 1 point; Natural Science (botany, biology, zoology), 2 points; Physical Science (chemistry, physics), 2 points; Trigonometry, 1 point; Astronomy 1, Civics 1, Geology 1, Physical Geography 1, Physiology and Hygiene 1, Political Economy 1.

(One point in any subject in a high school or academic course demands not less than five periods per week of forty-five minutes each for eighteen weeks.)

Amended May 6, 1907, as follows:

(c) An examination in the following branches: A. Required, 18 points: Mathematics, 4 points; English, 4 points; History, 2 points; *Latin, 4 points;* Science (taken from physics, chemistry, botany, zoology), 4 points.

B. Optional: (Same as before.)

Amended March 17, 1908, as follows:

(c) An examination in the following branches, totaling 30 points:

A. Required, 16 points.	Points
Mathematics—(Minimum, 2 years; maximum, 3 years.........	4
Algebra and plain geometry.	
English—(Minimum, 2 years; maximum, 4 years)...........	4
(a) English grammar.	
(b) Rhetoric and composition.	
Latin—(Minimum, see (b); maximum, 4 years)........	4
(a) Latin grammar.	
(b) Latin prose composition.	
(c) Reading four books of Cæsar or equivalent.	
Physics—(1 year). With laboratory work..................	2
History (1 year). Including civics and political economy......	2
Total required..................................	16

B. Elective, 14 points.	Points
ature (2 years) Only if taken after	
....	4
Spanish or Greek (4 years); not less than 1 year in any one sec (b).................	2
Advanced Mathematics—Solid Geometry and Trigonometry (½ year each)........................	1
Natural Science (1 year). Biology, 1 year, or Botany and Zoology, ½ year each..........................	2
Physical Science—(1 year). Chemistry..................	2
Earth Science—Physical Geography and Geology, ½ year each..	1
Physiology and Hygiene—(½ year)......................	1
Astronomy—(½ year)............................	1
Drawing—(½ year)............................	1

One point in any subject demands one period per week of not less than 45 minutes, for 18 weeks.

Two points equal 5 counts, or 1 unit, or 2 credits.

If only 4 hours per week are given in a subject, the year's work represents 4 counts (the minimum), and must be counted as such and not as 5 counts (the maximum).

(d) Certificates from reputable instructors [recognized by the superintendent hereinafter to be mentioned or] by any state board of medical examiners duly authorized by law, may be accepted in lieu of any part of this examination.

Amended March 19, 1906, as follows:

(d) Certificates from reputable instructors *recognized by any state board of medical examiners duly authorized by law or by the superintendents of public instruction in states not having a board of examiners,* may be accepted in lieu of any part of this examination.

Section 1 (e) was added May 21, 1910, as follows:

The university matriculation certificate of the members of the Association of American Universities may be accepted as a minimum requirement for admission.

Section 1 (d) and (e) were eliminated Feb. 28, 1911.

SEC. 2.—This examination must be conducted by or under the authority of the superintendent of public instruction [of the city or] state in which the college is located. In no case shall it be conducted by any person connected with the faculty, medical or otherwise, of the institution to which the student is seeking admission.

Amended March 19, 1906, as follows:

SEC. 2.—This examination must be conducted by or under the authority of the *board of examiners or* of the superintendent of public instruction of [the city or] state in which the college is located. In no case shall it be conducted by any person connected with the faculty, medical or otherwise, of the institution to which the student is seeking admission.

Amended March 21, 1910, as follows:

This examination must be conducted by or under the authority of the board of examiners [or of the superintendent of public instruction] of the state in which the college is located [*as provided for in Sec. 1, (d).*] In no case, etc. (same as before).

Amended Feb. 28, 1911, as follows:

SEC. 2—This examination must be conducted by or under the authority of the board of *medical* examiners of the state in which the college is located, *or by a duly authorized examiner of the college entrance examination board, or the authorized examiner of an accredited university, state or otherwise, or by an examiner whose certificates are accepted by accredited colleges or universities, or by a method approved by the judicial council of this association.*

SEC 3.—A student may be allowed to enter on his medical work conditioned in not more than six points, and these conditions must be removed by satisfactory examination before he is allowed to enter on the second year of his medical course.

By an amendment adopted Feb. 28, 1911, to become effective on and after Jan. 1, 1912, no entrance conditions are to be permitted, and Section 3 is re-worded to cover another subject, as follows:

SEC. 3.—The term "accredited" as applied to high schools, academies, colleges and universities means institutions of that type that have been investigated and are accredited by the state university of their respective states, by the North Central Association of Colleges and Secondary Schools, the Association of Colleges and Preparatory Schools of the Southern States, the Association of Colleges and Preparatory Schools of the Middle States and Maryland, the New England College Entrance Certificate Board, the Association of American Universities and the Association of State Universities, provided that such accrediting is based on Article III, Section 1, of this constitution.

SEC 4.—Colleges in membership in this Association may honor the official credentials presented by students from other colleges having the standard requirements maintained by members of this Association, excepting for the fourth year of the course, but no member of this Association shall admit a student to advanced standing without first communicating with the college from which such student desires to withdraw dean of such college a direct written to the applicant's [professional and mora exact work he has done in said college.]

Amended Feb. 28, 1911, to read:

Colleges in membership . . . without . . . receiving from the dean, *secretary or registrar* of such college a direct written communication certifying to the applicant's *standing. Credit for time or scholarship cannot be given beyond that of the college issuing the credentials, except by mutual agreement between the colleges.*

SEC. 5.—Candidates for the degree of Doctor of Medicine shall have attended four courses of study in four calendar years, each annual course to have been of not less than thirty (changed to *thirty-two* by amendment adopted March 21, 1910) teaching weeks' duration, and at least ten months shall intervene between the beginning of any course and the beginning of the preceding course.

SEC. 6.—Credit may be given to the holder of a Bachelor's degree from an approved college or university for any work in the medical branches which he has successfully completed in his college course, only so far as it is the full equivalent of corresponding work in the medical curriculum. The holder of such Bachelor's degree may also be given time credits of not exceeding one year, provided that such student has had at least 40 hours in physics, 144 hours in chemistry, 24 hours in osteopathy, 292 hours in human or comparative anatomy, 124 hours in histology, 85 hours in embryology, 145 hours in physiology and 46 hours in materia medica, provided that the applicant for such time credits satisfies the professors of the chairs mentioned in the medical school as to his proficiency in these first-year medical studies, and satisfies the examiner, as provided for in Section 2, Article III, that his studies for which the degree was conferred include the above requirements. Such student may be allowed to complete a course for the medical degree in not less than 31 months, provided he completes the remainder of the medical curriculum in that time.

This section was amended May 6, 1907, to read as follows:

SEC. 6.—No time credit shall be given to holders of a Bachelor's degree, but subject credit may be given on satisfactory examination. Four years of residence in a medical college shall be required of all candidates for the degree of Doctor of Medicine.

SEC 7.—A college which gives less than a four years' course of study, but does not graduate students, and is possessed of other required qualifications, may be admitted to membership.

SEC. 8.—Each student shall be obliged to attend 80 per cent. of the exercises in every annual course of study for which he seeks credit. No student shall be given credit on examination unless he attains a grade of at least 70 per cent. or its equivalent in any other marking system. And no student shall be graduated unless he shall have attained a passing grade in each and all subjects of the required curriculum.

This section was amended Feb. 28, 1911, by inserting in the first line, after the word "attend," "*not less than.*"

ARTICLE V.

SECTION 1.—*The* entire course of four years shall consist of at least 4,000 hours, divided into the subjects as shown in the following table, and no college shall be recognized that falls below this standard over 20 per cent. in any one branch or over 10 per cent in the total. Laboratory or clinic hours may be substituted for didactic hours.

(Continued on page 648)

TABLE 2.—DISTRIBUTION OF MEDICAL

Number.	NAME OF COLLEGE	1 Alabama.........549	2 Arizona.........10	3 Arkansas.........307	4 California.........356	5 Colorado.........143	6 Connecticut.......243	7 Delaware.........34	8 Dist. of Columbia.131	9 Florida.........167	10 Georgia.........710	11 Idaho.........25	12 Illinois.........1598	13 Indiana.........503	14 Iowa.........489	15 Kansas.........341	16 Kentucky.........359	17 Louisiana.........329	18 Maine.........151	19 Maryland.........291	20 Massachusetts....819	Number.

Art. V, Sec. 1, was eliminated Feb. 28, 1911, and the following was substituted:

Art. V. Section 1.—The entire course of four years shall consist of at least 4,000 hours for each student, and shall be grouped in divisions and subdivided into subjects; each division and subject to be allotted the number of hours as shown in the following schedule:

Division 1.—Anatomy, 710 Hours (18 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) Gross anatomy (including applied anatomy)	510	120	390
(b) Histologic and microscopic anatomy	135	30	105
(c) Embryology	75	30	45

Division 2.—Physiology and Chemistry, 600 Hours (15 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) Inorganic chemistry	180	60	120
(b) Organic chemistry	75	30	45
(c) Physiologic chemistry	104	30	75
(d) Physiology	240	140	100

Division 3.—Pathology, Bacteriology and Hygiene, 450 Hours (11.25 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) Bacteriology	135	30	105
(b) Hygiene and general dietetics	45	45	...
(c) Pathology	270	60	210

Division 4.—Pharmacology, Materia Medica and Therapeutics, 240 Hours (6 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) Pharmacology	105	40	65
(b) Materia medica and pharmacology	80	...	...
(c) Therapeutics	55	...	...

Division 5.—Medicine and Medical Specialties, 970 Hours (24.25 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) General medicine (including clinical microscopy)	640	...	...
(b) Pediatrics	150	...	...
(c) Nervous and mental diseases	105	...	...
(d) Jurisprudence, ethics and economics	30	...	...
(e) Dermatology and syphilis	45	...	...

Division 6.—Surgery and Surgical Specialties, 720 Hours (18 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) General surgery	510	...	...
(b) Orthopedic surgery	45	...	...
(c) Genito-urinary diseases	45	...	...
(d) Eye	60	...	...
(e) Ear, nose and throat	60	...	...

Division 7.—Obstetrics and Gynecology, 300 Hours (7.5 Per Cent.)

	Hours.	Lect. Rec. Dem.	Lab. Wk.
(a) Obstetrics	195	...	...
(b) Gynecology (including some abdominal surgery)	105	...	...

Colleges may reduce the number of hours in any subject not more than 20 per cent. provided that the total number of hours in a division is not reduced. Where the teaching conditions in a college are best subserved, the subject may be, for teaching purposes, transferred from one division to another. When didactic and laboratory hours are specified in any subject, laboratory hours may be substituted for didactic hours.

(Continued from opposite page)

The following section was added to Article V, May 6, 1907:

SEC. 2.—Each medical college in membership in the Association shall print in every annual catalogue or announcement a table of the total number of hours work given in said college, arranged both by subjects and years.

The following section was added to Article V, Feb. 28, 1911:

SEC. 3.—Each college in membership in this Association shall print annually a list of its students by classes.

The following colleges are members of the Association: Leland Stanford Junior University Department of Medicine, Palo Alto and San Francisco, Cal.; University of California, Medical Department, Berkeley, Los Angeles and San Francisco, Cal.; University of Southern California, Medical Department, Los Angeles, Cal.; University of Colorado, School of Medicine, Boulder and Denver, Colo.; George Washington University Department of Medicine, Washington, D. C.; Georgetown University School of Medicine, Washington, D. C.; Howard University Medical Department, Washington, D. C.; University of Illinois, College of Medicine, Chicago, Ill.; Northwestern University Medical School, Chicago, Ill.; Indiana University School of Medicine, Bloomington and Indianapolis, Ind.; Drake University College of Medicine, Des Moines, Iowa; State University of Iowa, College of Medicine, Iowa City, Iowa; Kansas Medical College, Medical Department of Washburn College, Topeka, Kan.; University of Kansas, School of Medicine, Lawrence and Rosedale, Kan.; University of Louisville, Medical Department, Louisville, Ky.; Medical Department of the Tulane University of Louisiana, New Orleans, La.; Baltimore Medical College, Baltimore, Md.; College of Physicians and Surgeons, Baltimore, Md.; Johns Hopkins University, Medical Department, Baltimore, Md.; University of Maryland, School of Medicine, Baltimore, Md.; Medical School of Howard University, Boston, Mass.; Tufts College Medical School, Boston, Mass.; Detroit College of Medicine, Detroit, Mich.; University of Michigan, Department of Medicine and Surgery, Ann Arbor, Mich.; University of Minnesota, College of Medicine and Surgery, Minneapolis, Minn.; University of Mississippi Medical Department, Oxford, Miss.; University of Missouri Department of Medicine, Columbia, Mo.; University Medical College, Kansas City, Mo.; St. Louis University School of Medicine, St. Louis, Mo.; Washington University Medical School, St. Louis, Mo.; University of Nebraska, College of Medicine, Lincoln and Omaha, Neb.; John A. Creighton Medical College, Omaha, Neb.; University of Buffalo, Medical Department, Buffalo, N. Y.; University and Bellevue Hospital Medical College, New York, N. Y.; Cornell University Medical College, Ithaca and New York, N. Y.; Syracuse University, College of Medicine, Syracuse, N. Y.; University of North Carolina, Medical Department, Chapel Hill, N. C.; Wake Forest College, School of Medicine, Wake Forest, N. C.; University of North Dakota, College of Medicine, University, N. D.; Western Reserve University, Medical Department, Cleveland, Ohio; Starling-Ohio Medical College, Columbus, Ohio; Ohio-Miami Medical College of the University of Cincinnati, Cincinnati, Ohio; State University of Oklahoma, School of Medicine, Norman, Okla.; Meharry Medical College, Medical Department of Walden University, Nashville, Tenn.; Vanderbilt University, Medical Department, Nashville, Tenn.; Medical College of Virginia, Richmond, Va.; University College of Medicine, Richmond, Va.; University of Wisconsin, College of Medicine, Madison, Wis.

The secretary-treasurer of the Association is Dr. Fred C. Zapffe, 3431 Lexington Street, Chicago.

COLLEGE NOTES

Colleges Closed During the Year.—Thirteen medical colleges have been closed during the year, eight of which were suspended and five by merger with other institutions. The list is as follows:

College of Physicians and Surgeons, Little Rock, Arkansas. Merged into the Medical Department of the University of Arkansas.

Denver and Gross College of Medicine, Denver, Colo. Merged into the University of Colorado School of Medicine.

American Medical Missionary College, Battle Creek, Mich., and Chicago. Merged into the College of Physicians and Surgeons, Chicago.

College of Medicine and Surgery, Physiomedical, Chicago. Absorbed by the Chicago College of Medicine and Surgery.

Reliance Medical College, Chicago. Discontinued.

Southwestern Homeopathic Medical College, Louisville, Ky. Merged into the Hahnemann Medical College and Hospital, Chicago.

Atlantic Medical College, Baltimore, Md., formerly the Southern Homeopathic Medical College. Suspended.

University Medical College, Kansas City, Mo. Suspended.

Knoxville Medical College (Colored), Knoxville, Tenn. Suspended.

College of Physicians and Surgeons, Memphis, Tenn. Merged with, and building to be occupied hereafter by, the Medical Department of the University of Tennessee, which is to be removed from Nashville.

University of Nashville, Medical Department, Nashville, Tenn. Dissolved its union with the University of Tennessee Medical Department and became extinct.

West Virginia University College of Medicine, Morgantown, W. Va. Closed.

The San Jose College of Medicine and Pharmacy of the San Thomas University, Manila, Philippine Islands, has been permanently closed.

This table gives an interesting study of the migration of medical students. It shows that of the 19,148 medical students coming from the various states and attending the medical schools of the United States during the session of 1910-11, 2,330 went to other parts of the country to study medicine. Groups A, B, C and D show where the students from each section go to study medicine. Group A shows where the students coming from the eastern section of the country went to study medicine. Section B shows the same for the students from the middle section of the country. Table C, students from the western section of the country, and Table D, students from the southern section. For example, Group A shows that 7,035 medical students came from the eastern section during 1910-11 and of that number 6,497 entered colleges of the east, 415 attended colleges of the middle states, 43 attended western colleges and 80 attended southern colleges. Figures for the last four college sessions are given and this permits an interesting study by states. For example, Kentucky furnished 635 students in 1908 but only 359 in 1911; nevertheless, where only 9.6 per cent. attended southern colleges in 1907-08, 17.2 per cent. attended southern colleges in 1910-11. Was this due to the fact that the south has better medical colleges now than in 1908 or to the fact that a large number of colleges in the middle section have adopted higher standards? These tables show also the to students coming from each state for each of the las well as from each section. For example, a study of that for each of the four years New York furnish medical students and about 93 per cent. of those stu the colleges of their home section. Group B of Table the southern section furnished 5,467 students for 1907-08 but only 4,848 for the session of 1910-11. also shows a larger percentage of students going to schools in 1911 than went to those schools in 1908; it that a smaller portion of students attended the colle middle states during 1911 than attended those schools in

(*Continued from opposite page*)

sum $20,000 is for medical research and $10,000 is to go toward the endowment of the university clinic.

Georgia.—The Atlanta College of Physicians and Surgeons received a gift of $5,000 from Dr. W. S. Elkin, which was expended in equipping the departments of embryology, histology and physiology.

—The Medical College of Georgia received $46,000 from the citizens of Augusta, for a new college building.

Illinois.—The legislature appropriated $120,000 for the College of Medicine of the University of Illinois (The College of Physicians and Surgeons, Chicago). This is $60,000 per year for two years.

—The sum of $65,000 has been donated by Mrs. Anna W. Phelps to provide a new site for the Hahnemann Hospital, Chicago. In his will the late Erskine M. Phelps had bequeathed $30,000 for a new hospital building and $75,000 for a nurses home. It is stated that the Hahnemann Medical College intends to sell its present college building and will erect another building on the new site.

—A gift of $250,000 was received by Northwestern University Medical School, Chicago, from Mr. James A. Patten, to endow and maintain a chair of medical research.

Indiana.—Property valued at $200,000 was donated by Dr. and Mrs. R. W. Long of Indianapolis toward the establishing of a state hospital under the direction of the Indiana University School of Medicine. The school also received a bonus of $25,000 annually through the last legislature.

Iowa.—One new building at a cost of $30,000 has been completed by the Drake University College of Medicine, Des Moines, and a second building which will cost a like sum is now in course of construction.

—An addition has been made to the University Hospital of the State University of Iowa College of Medicine, at a cost of $100,000.

Maryland.—The University of Maryland School of Medicine has received pledges amounting to $7,250 toward an endowment for the department of pathology.

This table gives an interesting study of the migration of medical students. It shows that of the 19,148 medical students coming from the various states and attending the medical schools of the United States during the session of 1910-11, 2,330 went to other parts of the country to study medicine. Groups A, B, C and D show where the students from each section go to study medicine. Group A shows where the students coming from the eastern section of the country went to study medicine. Section B shows the same for the students from the middle section of the country. Table C, students from the western section of the country, and Table D, students from the southern section. For example, Group A shows that 7,035 medical students came from the eastern section during 1910-11 and of that number 6,497 entered colleges of the east, 415 attended colleges of the middle states, 43 attended western colleges and 80 attended southern colleges. Figures for the last four college sessions are given and this permits an interesting study by states. For example, Kentucky furnished 635 students in 1908 but only 359 in 1911; nevertheless, where only 9.6 per cent. attended southern colleges in 1907-08, 17.2 per cent. attended southern colleges in 1910-11. Was this due to the fact that the south has better medical colleges now than in 1908 or to the fact that a large number of colleges in the middle section have adopted higher standards? These tables show also the total number of students coming from each state for each of the last four years as well as from each section. For example, a study of Group A shows that for each of the four years New York furnished over 2,100 medical students and about 93 per cent. of those students attended the colleges of their home section. Group D of Table 3 shows that the southern section furnished 5,467 students for the session of 1907-08 but only 4,848 for the session of 1910-11. This section also shows a larger percentage of students going to the eastern schools in 1911 than went to those schools in 1908; it also shows that a smaller portion of students attended the colleges of the middle states during 1911 than attended those schools in 1908.

sum $20,000 is for medical research and $10,000 is to go toward the endowment of the university clinic.

Georgia.—The Atlanta College of Physicians and Surgeons received a gift of $5,000 from Dr. W. S. Elkin, which was expended in equipping the departments of embryology, histology and physiology.

—The Medical College of Georgia received $46,000 from the citizens of Augusta, for a new college building.

Illinois.—The legislature appropriated $120,000 for the College of Medicine of the University of Illinois (The College of Physicians and Surgeons, Chicago). This is $60,000 per year for two years.

—The sum of $65,000 has been donated by Mrs. Anna W. Phelps to provide a new site for the Hahnemann Hospital, Chicago. In his will the late Erskine M. Phelps had bequeathed $30,000 for a new hospital building and $75,000 for a nurses home. It is stated that the Hahnemann Medical College intends to sell its present college building and will erect another building on the new site.

—A gift of $250,000 was received by Northwestern University Medical School, Chicago, from Mr. James A. Patten, to endow and maintain a chair of medical research.

Indiana.—Property valued at $200,000 was donated by Dr. and Mrs. R. W. Long of Indianapolis toward the establishing of a state hospital under the direction of the Indiana University School of Medicine. The school also received a bonus of $25,000 annually through the last legislature.

Iowa.—One new building at a cost of $30,000 has been completed by the Drake University College of Medicine, Des Moines, and a second building which will cost a like sum is now in course of construction.

—An addition has been made to the University Hospital of the State University of Iowa College of Medicine, at a cost of $100,000.

Maryland.—The University of Maryland School of Medicine has received pledges amounting to $7,250 toward an endowment for the department of pathology.

This table gives an interesting study of the migration of medical students. It shows that of the 19,148 medical students coming from the various states and attending the medical schools of the United States during the session of 1910-11, 2,330 went to other parts of the country to study medicine. Groups A, B, C and D show where the students from each section go to study medicine. Group A shows where the students coming from the eastern section of the country went to study medicine. Section B shows the same for the students from the middle section of the country. Table C, students from the western section of the country, and Table D, students from the southern section. For example, Group A shows that 7,035 medical students came from the eastern section during 1910-11 and of that number 6,497 entered colleges of the east, 415 attended colleges of the middle states, 43 attended western colleges and 80 attended southern colleges. Figures for the last four college sessions are given and this permits an interesting study by states. For example, Kentucky furnished 635 students in 1908 but only 359 in 1911; nevertheless, where only 9.6 per cent. attended southern colleges in 1907-08, 17.2 per cent. attended southern colleges in 1910-11. Was this due to the fact that the south has better medical colleges now than in 1908 or to the fact that a large number of colleges in the middle section have adopted higher standards? These tables show also the total number of students coming from each state for each of the last four years as well as from each section. For example, a study of Group A shows that for each of the four years New York furnished over 2,100 medical students and about 93 per cent. of those students attended the colleges of their home section. Group D of Table 3 shows that the southern section furnished 5,467 students for the session of 1907-08 but only 4,848 for the session of 1910-11. This section also shows a larger percentage of students going to the eastern schools in 1911 than went to those schools in 1908; it also shows that a smaller portion of students attended the colleges of the middle states during 1911 than attended those schools in 1908.

Endowments, New Medical Buildings and Hospitals

Alabama.—The state legislature made an appropriation of $25,000 per year for the running expense of the Medical Department of the University of Alabama, Mobile.

Connecticut.—Yale Medical School received a donation of $30,000 from Francis E. Loomis of the class of 1864. Of this

(Continued from opposite page)

sum $20,000 is for medical research and $10,000 is to go toward the endowment of the university clinic.

Georgia.—The Atlanta College of Physicians and Surgeons received a gift of $5,000 from Dr. W. S. Elkin, which was expended in equipping the departments of embryology, histology and physiology.

—The Medical College of Georgia received $46,000 from the citizens of Augusta, for a new college building.

Illinois.—The legislature appropriated $120,000 for the College of Medicine of the University of Illinois (The College of Physicians and Surgeons, Chicago). This is $60,000 per year for two years.

—The sum of $65,000 has been donated by Mrs. Anna W. Phelps to provide a new site for the Hahnemann Hospital, Chicago. In his will the late Erskine M. Phelps had bequeathed $30,000 for a new hospital building and $75,000 for a nurses home. It is stated that the Hahnemann Medical College intends to sell its present college building and will erect another building on the new site.

—A gift of $250,000 was received by Northwestern University Medical School, Chicago, from Mr. James A. Patten, to endow and maintain a chair of medical research.

Indiana.—Property valued at $200,000 was donated by Dr. and Mrs. R. W. Long of Indianapolis toward the establishing of a state hospital under the direction of the Indiana University School of Medicine. The school also received a bonus of $25,000 annually through the last legislature.

Iowa.—One new building at a cost of $30,000 has been completed by the Drake University College of Medicine, Des Moines, and a second building which will cost a like sum is now in course of construction.

—An addition has been made to the University Hospital of the State University of Iowa College of Medicine, at a cost of $100,000.

Maryland.—The University of Maryland School of Medicine has received pledges amounting to $7,250 toward an endowment for the department of pathology.

(Continued on next page)

Massachusetts.—Harvard Medical School was left $22,000 by the will of the late Samuel Hubbard Scudder, which will revert to the school on the death of the testator's sister, Mrs. Mary E. Blatchford. Also $4,000 in cash and all his medical books and scientific apparatus were received through the will of the late Dr. Henry P. Bowditch.

—The medical building of the Tufts College Medical School has been enlarged at an expense of about $50,000.

Missouri.—The Robert A. Barnes Hospital is to be erected on the campus of the Washington University School of Medicine on King's highway, St. Louis, at a cost of $1,500,000. It will consist of a group of ten buildings.

—A new hospital for the clinical department of the St. Louis University School of Medicine has been erected by the Sisters of Mercy at a cost of $350,000.

New York.—The Medical Department of the University of Buffalo has erected an addition to its college building at a cost of $20,000.

—An additional donation of $3,820,000 has been given by John D. Rockefeller for the Rockefeller Institute of Medical Research. This brings his total gifts for the institute to $8,240,000.

—Fordham University School of Medicine is erecting a new college building, the approximate cost of which, when completed, will be $100,000.

—A gift of $1,300,000 has been pledged for the perfection of the affiliation of the Presbyterian Hospital and the medical school of Columbia University. The gift was made through Edward H. Harkness and is believed to have come from members of his family. He himself contributes $300,000 for the erection of a surgical pavilion to be equipped with modern appliances and also a complete laboratory for advanced research work. More recently $100,000 has been given to this hospital by the will of Miss Adele A. Dortic and a second $100,000 by the Supreme Court decision in regard to the will of Edward O. Kindberg.

—Columbia University received an anonymous gift of $10,000 annually for four years, a total of $40,000, to be used in surgical research.

—A sum of $10,000 has been pledged by the alumni of the New York Homeopathic Medical College and Hospital for the maintenance of the bacteriological laboratory at the college.

Nebraska.—The Nebraska legislature appropriated $100,000, which will be used to establish all four years of the medical course of the University of Nebraska College of Medicine on the new campus in Omaha.

North Carolina.—A new medical building has been erected on the campus of the University of North Carolina at an approximate cost of $37,000.

Ohio.—Western Reserve University has received from Mr. H. M. Hanna a gift of $250,000 toward an endowment fund for the Medical Department.

—A new addition to the laboratory building of the Starling-Ohio Medical College has been erected at a cost of $10,000.

—Ohio-Miami Medical College of the University of Cincinnati received $50,000 by the will of the late Dr. Francis Brunning as an addition to the endowment fund.

Oregon.—The legislature recently made an appropriation of $30,000 for the Medical Department of the University of Oregon.

Pennsylvania.—The University of Pennsylvania received a gift of $100,000 to be used in establishing a "Benjamin Rush Chair of Physiologic Chemistry." The chair has been established and Dr. Alonzo E. Taylor has been chosen for the place.

—A modern clinical amphitheater was erected for the Woman's Medical College of Pennsylvania at a cost of $22,500. The college also received a bequest of $3,000 by the will of the late Annie Shoemaker.

—The Hahnemann Medical College and Hospital of Pennsylvania is said to have received a gift of $100,000 to establish a chair in materia medica.

South Carolina.—A new building is being erected by the Medical College of South Carolina which will cost approximately $75,000.

Tennessee.—A special donation of $150,000 was made by Mr. W. K. Vanderbilt to purchase the sixteen-acre campus of the Peabody Normal College for the Medical and Dental Departments of Vanderbilt University. Vanderbilt University has now assumed all responsibility financially and otherwise for its medical department.

—Meharry Medical College, Nashville, has been promised $10,000 by Mr. Andrew Carnegie for the completion of Hubbard Hospital, on condition that another $10,000 is raised from other sources.

Virginia.—The University College of Medicine, Richmond, is erecting a new college building to replace the one destroyed by fire in January, 1910. The approximate cost will be $135,000.

Wisconsin.—An anonymous donor contributed $5,000 to the maintenance fund of the Wisconsin College of Physicians and Surgeons, Milwaukee.

Philippine Islands.—The new Philippine General Hospital at Manila has been completed. It is located on the same campus as the Philippine Medical School, now the College of Medicine and Surgery of the University of the Philippines.

Total Donations for the Year.—Although there were doubtless other instances of gifts or new buildings not reported to us, the above items show that at least $855,500 were spent during the year for new medical buildings; $459,000 were received in straight donations; $215,000 were given for the endowment of special chairs; $266,130 for the endowment of the medical schools proper and $150,000 for a new campus. Therefore, for purposes directly concerned with medical education a total of $1,945,630 was provided for. Besides this sum, $3,755,000 were given to establish teaching hospitals and $310,000 for medical research in medical schools, increasing the total to $6,010,630. This does not include an additional sum of $3,820,000 given by Mr. Rockefeller for medical research at the Rockefeller Institute.

Other College Notes

Adopted Hospital Year.—The University of Minnesota College of Medicine and Surgery has adopted the requirement that beginning this fall all matriculants must have attended a five-year course before graduation and that the fifth or last year must have been spent as an intern in a hospital satisfactory to the college.

Adopt Concentration Method.—The concentration method of teaching medicine, modifications of the method employed at the Harvard Medical School, have been adopted by Syracuse University College of Medicine, Syracuse, N. Y.; Drake University College of Medicine, Des Moines, Iowa, and the State University of Iowa College of Medicine, Iowa City.

To Save Old Medical Building.—The alumni of the Department of Medicine and Surgery of the University of Michigan are endeavoring to raise $50,000 to save the old medical building as a memorial to the medical department. This amount will be sufficient to reconstruct the interior without changing the outside appearance.

Special Chair in Preventive Medicine.—A special chair in preventive medicine has been established at the Washington University Medical School and Dr. David L. Edsall, formerly professor of medicine in the University of Pennsylvania has been selected to occupy the place.

Diploma Mill Again Closed.—The Gate City Medical College formerly located at Texarkana and which was reported to have been closed in 1907, reopened in Dallas in 1910. Circulars were sent out offering to give courses by mail and several of these were sent by the recipients to the office of the American Medical Association.[1] Some decoy correspondence was carried on with the dean, Dr. J. W. Decker. This correspondence and several of the circulars were forwarded to the Texas State Medical Association, who placed the matter in the hands of their attorney, Mr. James N. Wilkerson. Mr. Wilkerson succeeded in purchasing outright two diplomas from Decker for $50 on December 29, 1910. Decker was arrested and a bill of indictment was found against him by the Federal Grand Jury for fraudulent use of the mails. In May, 1911, Decker was convicted and sentenced to fifteen months of hard labor at Fort Leavenworth, Kansas. At the trial it was shown that the defunct College of Physicians and Surgeons had been consolidated with this "college" and that the entire equipment of the consolidated institution consisted of a stove, a table, two chairs, a manikin, a blackboard and a defective skeleton.

---

[1] THE JOURNAL A. M. A., March 18, 1911, p. 839.

Cooperative Course in Public Health.—The board of directors of the University of Cincinnati has arranged to cooperate with the health department of the city of Cincinnati to provide for the medical students a training in public health work. Each of the two upper classes will be divided into four groups and each group will be assigned to the board of health where the students will do chemical and bacteriological work (such as the examination of milk and water, the making of tests for typhoid fever, tuberculosis, diphtheria, etc.) They will also do sanitary inspection and fumigation; trace the sources of infections; make food, dairy, bakery, barber-shop and school inspections; practice preventive inoculation and vaccination; study the methods of disposal of sewage and of the dead and serve in the city dispensaries. Students will also participate in the work of the Antituberculosis League, and in the office work of the board of health, studying methods of making reports, compiling statistics and keeping records. Two groups of students, one from each class, will be assigned to the board of health at one time and these two groups will serve for one month after which two other groups will be assigned until all students have taken the work. This work is designed to send out physicians who will be better acquainted with public health problems and better trained to take up the work of disease prevention.

Public Health Course in Wisconsin.—In conjunction with the State Department of Public Health, the University of Wisconsin has arranged for a special course for public health officers to begin this fall. The course will extend over one year and will lead to a Diploma of Public Health. It will be open to those who have received a degree in medicine or in medical or sanitary science and desire to fit themselves especially for public health work. The subjects offered are as follows:

First Semester.—1. Bacteriology for Health Officers. 2. Physi-
the chemistry of food, air, water,
4. Medical Zoology.
Bacteriology, Pathology and Hygiene
for Health Officers. To include bacteriology of air, water, food and soils, epidemiology, diseases of animals transferable to man, occupational diseases, etc. 2. Microscopical Examination of Drugs and Foods. 3. Public Health Administration and Vital Statistics. 4. Practical Field Work. 5. Hydrology.

In addition to the course above outlined, it is planned to have a conference of public health officers of the villages and cities of Wisconsin at the state university once in two years. The recent legislature passed a bill authorizing the secretary of the State Board of Health to call a conference of this kind and authorizing the expenses of such officers who attend such a conference to be paid by the village or city from which they come.

FOREIGN COLLEGE NOTES

Adelaide, Australia.—The medical school in the University of Adelaide, Australia, was founded in 1883, but the complete curriculum was not offered until 1886. The course covers five years of nine months each in addition to preliminary work, including courses in physics, chemistry and elementary biology. The faculty numbers 17. The total enrolment of medical students in 1910 was 73; graduates, 8. The amount received from medical students' fees in 1910 was 2,172 pounds (about $10,860), while the amount expended for medical teaching was 3,072 pounds (or about $15,360). The school has endowments amounting to 36,000 pounds (about $180,000).

Canton, China.—The University Medical School of Canton, China, was organized in 1908 by the Christian Association of the University of Pennsylvania as a modern missionary enterprise. A dispensary was opened. In the first year, 3,839 patients were treated, and in the second year 4,203. A hospital to cost $16,500 is now being erected. The first class consisting of four students was enrolled in February, 1910. That the standards of its work may be guaranteed it is desired to bring the Medical School and Hospital into some direct official relationship with the University of Pennsylvania. It is now affiliated with the Canton Christian College, an institution incorporated under the regents of the State of New York, with assets of $180,000, having a faculty of twelve American professors, assisted by fourteen Chinese instructors. The campus of the Canton Christian College consists of forty-eight acres, adjoining the eight-acre tract belonging to the University Medical School.

—Reports have also been received from the South China Medical College at Canton, which during 1910 enrolled thirty-six students. Eleven physicians are engaged in teaching. A four-year course of over 900 hours each year is required. Before completing his course the student is required to do six months' clinical work in the hospital wards. In the hospital 1,928 patients were cared for during 1910, and in the out-patient department, 17,962. There were 1,747 surgical operations.

Siena, Italy.—The Royal University of Siena, Italy, gives a medical course covering six years, including preliminary courses in physics, chemistry and biology. The medical faculty numbers twenty. The annual session begins early in November and extends to the last week in July of each year. During 1909-10 the enrolment of medical students was forty-nine, including nine candidates for graduation.

Halifax, Nova Scotia.—Dalhousie University has taken over the Halifax Medical College and hereafter assumes full control, financially and otherwise. The college is to be completely reorganized and the name has been changed to the Dalhousie Medical College, Medical Faculty of Dalhousie University.

Zurich, Switzerland.—The total enrolment of medical students at the University of Zurich during last year was 393, and of this number 124 were women. The faculty is made up of eighteen professors and twenty-seven docents, a total of forty-five. The summer semester begins in April and the winter semester in October of each year. The course covers five years, including preliminary courses in physics, chemistry and biology.

Beirut, Syria.—In France, 100,000 francs, or more than $20,000, have been subscribed for the enlargement of the Beirut Medical School at Beirut, Syria. The number of students enrolled is reported at 250, and the new building will increase the capacity to 400. A new teaching hospital is also planned.

—The School of Medicine of the Syrian Protestant College of Beirut, Syria, was organized in 1867, the first class graduating in 1871. The course covers four years of thirty-five weeks each. Its faculty numbers fourteen. The total enrollment for 1909-10 was 138; graduates, eighteen. Johanniter Hospital is under the care of the medical school. It has eighty-three beds and over 800 patients were admitted during the year. In the policlinic, the out-patient department, over 13,000 cases were treated during the year. The school possesses a medical library of over 1,800 volumes and several prominent medical journals, American, English and French.

Montpellier, France.—The medical course at the University of Montpellier extends over four years. For admission a diploma from a seven-year gymnasium or lyceum is required and in addition to this the student must complete a year in the college of science devoted to physics, chemistry and biology. During the session of 1909-10, 729 medical students were enrolled and 133 were granted degrees. Of this number 120 received state diplomas and thirteen the diploma of the university. Of the 729 students, 650 were in regular attendance, the other seventy-nine being absent on military duty or for other cause.

Montreal, Canada.—The Medical Faculty of McGill University is now occupying the new buildings erected during 1909 and 1910 at a cost of 450,000, to replace those destroyed by fire in April, 1907. The money was provided by Lord Strathcona, who in June, 1911, gave an additional $100,000 for equipment.

SATURDAY, AUGUST 19, 1911

MEDICAL EDUCATION IN THE UNITED STATES

The tabulated statistics herewith presented (pages 642 to 651) are for the year ending June 30, 1911, and are based on signed reports received directly from the medical colleges, or from other reliable sources. We wish here to acknowledge the courtesy and cooperation of the officials of the medical colleges which have made the compilation of these complete statistics possible.

STATISTICS OF COLLEGES

On pages 642 to 644 is Table 1, which gives all the colleges in session during 1910-11, the population of the city in which each college is located, the number of students, men and women, registered during the year, the number of 1911 graduates, men and women, the number of graduates holding collegiate degrees, the number of teachers for each college, the number of weeks of actual work in the college year, the total fees for each year, the executive officer of the college and the dates of beginning and ending of the next session. The figures in heavy-faced type show the totals by states. Beginning on page 630 are given essential facts concerning all medical colleges, arranged by states.

NUMBER OF MEDICAL STUDENTS

The total number of medical students (matriculants) in the United States for the year ending June 30, 1911, excluding special students, was 19,786, a decrease of 1,740 below 1910, a decrease of 2,359 below 1909, a decrease of 2,816 below 1908, and a decrease of 8,356 below 1904, when the highest number of students was enrolled. In fact, it is the lowest number since The Journal began compiling these statistics in 1900. Of the total number of students, 18,414 were in attendance at the regular colleges, 890 at the homeopathic, 433 at the eclectic, and 49 at the physiomedical colleges. The attendance at the regular colleges shows a decrease of 1,722 below that of last year, of 2,140 below 1909, and 2,522 below 1908. In the homeopathic colleges there was an increase of 23 above the attendance of 1910, but a decrease of 9 below the total for 1909. The eclectic colleges show a decrease of 22 below 1910, but an increase of 20 above 1909. The physiomedical colleges had the same number as last year, 49 students, as compared with 52 in 1909, and 90 in 1908.

TABLE 4.—Medical College Attendance

Year.	Regular.	Homeopathic.	Eclectic.	Physio-Med.	Nondescript.	Total.
1880	9,776	1,220	830	...	...	11,826
1890	13,521	1,164	719	...	...	15,404
1900	22,710	1,909	522	...	...	25,171
1901	23,816	1,683	661	80	144	26,417
1902	24,878	1,617	765	91	150	27,501
1903	24,930	1,408	848	149	190	27,615
1904	23,662	1,309	1,014	123	234	28,142
1905	24,119	1,104	578	114	232	26,147
1906	23,116	1,085	644	110	249	25,204
1907	22,303	1,039	545	97	292	24,276
1908	20,936	891	479	90	206	22,602
1909	20,554	899	413	52	227	22,145
1910	20,136	867	455	49	19	21,526
1911	18,414	890	433	49	...	19,786

GRADUATES

The total number of graduates for the year ending June 30, 1911, was 4,273, a decrease of 167 below 1910, of 242 below 1909, of 468 below 1908 and of 707 below 1907. It is the lowest number graduating since The Journal began compiling these statistics, and is 181 less than the number graduated in 1890. The total this year is 1,474 less than in 1904, when there were 5,747 graduates. The percentage of graduates to matriculants was 21.6 this year, as compared with 20.7 in 1910, 20.1 in 1909 and 21.0 in 1908. The number of graduates from the regular colleges was 4,006, or 107 less than in 1910, 157 less than in 1909, and 364 less than in 1908. From the homeopathic colleges there were 152 graduates, or 31 less than in 1910, 57 less than in 1909, and 63 less than in 1908. The eclectic colleges graduated 110, 4 less than last year, but 26 more than in 1909. The physiomedical colleges had 5 graduates this year, as compared with 16 last year and 15 in 1909.

TABLE 5.—Medical College Graduates

Year.	Regular.	Homeopathic.	Eclectic.	Physio-Med.	Nondescript.	Total.
1880	2,673	380	188	..	..	3,241
1890	3,853	380	221	..	..	4,454
1900	4,715	413	86	..	..	5,214
1901	4,879	387	148	18	12	5,444
1902*	4,508	336	138	16	11	5,009
1903	5,088	420	149	24	17	5,698
1904	5,190	371	146	20	20	5,747
1905	5,126	276	153	22	23	5,600
1906	4,841	286	186	22	29	5,364
1907	4,591	225	121	11	32	4,980
1908	4,370	215	116	12	28	4,741
1909*	4,163	209	84	15	44	4,515
1910*	4,113	183	114	16	14	4,440
1911	4,006	152	110	5	..	4,273

* The figures for these years include some corrections made since the last Educational Number was published.

Of the 4,273 medical graduates, 705, or 16.5 per cent., were reported to hold also degrees in arts or science, as compared with 15.3 per cent. last year and 15.6 per cent. in 1909. As will be noted by referring to Table 10, of the 705 graduates holding baccalaureate degrees, 102, the largest number, came from Illinois colleges, followed by 94 from Maryland, 91 from Massachusetts, 81 from Pennsylvania and 76 from New York colleges. It is expected that in future the percentage of college graduates entering medicine will increase since more medical schools are requiring college work for admission.

WOMEN IN MEDICINE

During the past year there were 680 women studying medicine, a decrease of 227 below 1910, and a decrease of 241 below 1909. The percentage of all medical students was 3.4 as compared with 4.2 last year. There were 159 women graduates this year, or 3.7 per cent. of all graduates. In 1910 there were 907 women students and 157 graduates, while in 1909 there were 921 women students and 162 graduates. Of all the women matriculants, 134 (17.7 per cent.) were in attendance at the two medical colleges for women, as compared with 155 (17.1 per cent.) in 1910, 169 (18.4 per cent.) in 1909 and 186 (22.3 per cent.) in 1908. The remaining 546 (80.3 per cent.) were matriculated in coeducational colleges. From the two women's colleges, there were 36, or 22.6 per cent., of all women graduates, as compared with 41 (26.1 per cent.) in 1910 and 33 (20.3 per cent.) in 1909. There were 123, or 80.3 per cent., of all women graduates who secured their degrees from coeducational colleges.

NUMBER OF COLLEGES

Since June 30, 1910, 13 colleges (mentioned on page 649) have either suspended or have merged into others, leaving 120 medical colleges still existing. The regular colleges number 101, a decrease of 10 since last year. The homeopathic colleges number 12, a decrease of 1 since last year. Of the eclectic colleges the number is 7, the same as last year. Among the 13 colleges which closed during the year, were included the last of the physiomedical colleges, and the last of the unclassifiable colleges.

1911..........	101	12	7	..	..	120

During the past seven years, 64 medical colleges have ceased to exist, either through merger or otherwise. During the same time, however, 18 new colleges were organized, leaving a net decrease of 46. While the total number of colleges is smaller, the percentage of higher-grade, stronger medical colleges, has been considerably increased.

LENGTH OF TERMS

The length of term of each college fluctuates somewhat from year to year, but on the whole, during the last eleven years there has been a decided lengthening of college terms. This has reference to the weeks of actual work, exclusive of holidays. There were no colleges this year which reported sessions shorter than twenty-seven weeks, whereas in 1901 there were 58. There were only 6 colleges having sessions of twenty-seven or twenty-eight weeks, or 2 less than last year, and 40 less than in 1903. There are 16 colleges claiming courses of twenty-nine or thirty weeks of actual work, and 37, the largest number, claim courses of thirty-one or thirty-two weeks. Of the 120 colleges now existing, 97, or over 80 per cent., now claim to require from 31 to 36 weeks of actual work, exclusive of holidays, as compared with 30 per cent. in 1901, 42 per cent. in 1904, and 76 per cent. last year. The one college claiming a course longer than thirty-six weeks is a night school. It would require twelve or fourteen years of the usual night-school study, however, to obtain the equivalent of four years of thirty weeks each in one of the better day colleges.

TABLE 8.—COLLEGE TERMS

	23 to 26 weeks.		27 to 28 weeks.		29 to 30 weeks.		31 to 32 weeks.		33 to 34 weeks.		35 to 36 weeks.		Over 36 weeks.

TUITION AND OTHER FEES

Special attention is called in Table 1 to the total amount charged by the various colleges for tuition, matriculation, laboratory and graduation fees per annum for each student. In Table 9, the 120 colleges have been grouped according to the amount of fees charged and according to their grouping by the Council on Medical Education in Classes A, B, or C.

Thirty-five colleges charge fees of $100 or less per year, 70 colleges charge between $100 and $175, and 15 colleges charge above $175. Of the 35 colleges charging $100 or less, 18, or over 50 per cent., were listed among Class A (acceptable) colleges[1] by the Council on Medical

---

[1] For complete classification see THE JOURNAL A. M. A., June 18, 1910, pp. 2061 and 2062.

TABLE 9.—College Fees

Total Fees.	Number of Colleges.			
	Class A.*	Class B.	Class C.	Total.
$ 50 or less	2	..	..	2
50 to $ 75	8	2	..	10
75 to 100	8	6	9	23
100 to 125	14	10	10	34
125 to 150	13	7	..	20
150 to 175	12	2	2	16
175 to 200	9	1	..	10
200 or above	4	..	..	5

* Based on the classification of medical colleges prepared by the Council on Medical Education.

Education, 8 were among Class B colleges, and only 9 of them are found among the Class C colleges. Among the 18 Class A colleges having these low fees are to be found the schools of medicine of the state universities of Colorado, Iowa, Mississippi, Missouri, North Dakota, South Dakota and Utah. On the other hand, 12 colleges listed by the Council in Class C charge fees of over $100 per year for each student. This clearly refutes the assertion made by some inferior colleges that they are needed for the sake of "the poor boy who wants to udy medicine." Although 25 colleges listed in Class charge fees ranging from $150 to $275 per year for each student, the actual expense for teaching that student in these colleges ranges from $300 to $600 or even more per year.

DISTRIBUTION OF MEDICAL STUDENTS

Table 2, on pages 646 to 649, shows from what states the students come who were in attendance at each medical college during the session of 1910-11. The influence of the proximity of the medical school is seen in the fact that states having medical colleges contribute more students in proportion to the population than those which have no colleges, as shown by the dark zone of larger figures running diagonally down the page. A comparison of this table with the large tables based on state board examinations[2] which show the distribution of the alumni of each college, is interesting. The college which has widely distributed alumni usually has a student body from an equally large number of states.

The state furnishing the largest number of students this year was New York, with 2,162. Pennsylvania contributed 1,799 and Illinois 1,598. The next states, in the order of the number of students contributed, are: Ohio, 859; Massachusetts, 819; Texas, 704; Missouri, 620, and Indiana, 503. Four states had less than 20 each, these being New Mexico and Wyoming, each 11; Arizona 10, and Nevada 4. There were 59 students from Hawaii, Porto Rico and the Philippine Islands and 579 students from foreign countries.

In Table 3, on pages 650 and 651, the totals coming from each state for the last four years may be seen. For instance, the number coming from New York has remained nearly the same, over 2,100 for each of the four years, while the number from Pennsylvania has decreased from 2,159 in 1909 to 1,799 in 1911. Illinois, also, shows a decrease from 1,749 in 1908 to 1,598 in 1911. On the other hand, a few states, for example Rhode Island, North Dakota, South Dakota and Georgia show an increase. In the last-named state, this may be due to the continuation of low educational standards.

MIGRATION OF MEDICAL STUDENTS

Table 3 also shows the number of students of each section of the country who attended medical schools of that section, and the number who attended medical colleges of other sections. Section A gives the figures for students from the eastern states; Section B, for students from the middle states; Section C, for students from the western states, and Section D, for students from the southern states. Figures are given for the four college years 1907-8, 1908-9, 1909-10 and 1910-11. The differences in the figures for the four years show the fluctuation due to the exit of the graduating classes, to the ingress of the new freshmen and to the comparatively few who left the colleges of one section and went to those of other sections. At the bottom of Section D appear the averages of the totals for the four years. Percentages are given in order to permit of comparisons. The eastern section has long held the largest place in medical education, and, as would be expected, still has the smallest percentage of students leaving to attend colleges in other sections, the percentage of those remaining in the eastern section being 92.3. The middle section is a close second, with 90.5 per cent. of its own resident students studying medicine in the home section. The southern section has 83.8 per cent. of its medical students studying in its own colleges, while the western section, having the smallest number of colleges, naturally has a smaller proportion of students (55 per cent.) attending in that section. Of the students who migrate from the middle and southern sections, the largest proportions go east while of those from the western section, the largest proportion attends colleges of the middle section. Altogether 2,330 students attended colleges outside of the section in which they lived during the session of 1910-1911. Of this number 998, or 42.6 per cent., went to the eastern section; 895, or 38.6 per cent., went to the middle section; 237, or 10.2 per cent., went to the southern section, and 200, or 8.6 per cent., went to the western section.

---

THE YEAR IN MEDICAL EDUCATION

There have been several important developments in medical education during the past year. One was the beginning of the requirement for admission of one or two years of collegiate work by 22 of the better-class medical schools of the United States, making a total of 41[3] which are now enforcing the higher standard. Another important development was the action taken by the Association of American Medical Colleges providing that after Jan. 1, 1912, students with entrance conditions are not to be accepted by colleges in membership in that organization. One more state licensing board, that of Utah, adopted as its minimum requirement of preliminary education a year of collegiate work, and the board of Colorado has increased its requirement from one to two years of collegiate work. There are, therefore, nine states[3] that have adopted this higher standard of preliminary education. Another feature of the year is the increased development of special courses in tropical medicine and in public health work.[4] Still another, and probably the most important feature of the year, however, is the large amount of money given for medical education.[5] The amount probably exceeds the gifts of any previous year, and insures an even greater development for medical education in the immediate future. Indeed, the outlook for medical education from every point of view is very encouraging.

DICTATOR McCABE

When it was first announced that Congress had called for an investigation of the facts leading to the charges preferred against Dr. Wiley by Messrs. McCabe, Dunlap and Wickersham, THE JOURNAL expressed the opinion that no one would welcome such an investigation more than would Dr. Wiley, unless it was the general public. Although the body created by Congress to look into this matter has been in existence but a few days, the mass of evidence already presented shows how accurate THE JOURNAL's statement was. Every point brought out so far has put Dr Wiley in a still more favorable light, while at the same time it has proved how well founded is the lack of confidence which the public has in those who are fighting him. It has been shown conclusively that Secretary Wilson — unknowingly, probably — has been a passive tool of those vast interests which have made their millions by poisoning the country's food and sophisticating its drugs.

The active partner in this attempt to nullify the national pure food law and make its action abortive is Solicitor McCabe. According to the evidence presented, McCabe both falsified and expurgated the account of a court proceeding in at least one pure food case. A firm pleaded guilty to the charge, brought by Dr. Wiley's assistants, that certain soft drinks contained "cocain, benzoic acid and coal tar dye." Mr. McCabe would not permit this judgment to be made public in that form, but when the printer's "proof" came he erased the words "benzoic acid" and substituted the word "caffein." This, of course, makes the government report of the case an official falsehood, but apparently McCabe feels that falsifying is permissible when it is done in the interest of the conservation of sodium benzoate. The fact of the matter is, the real power behind the throne—so far as the administration of the Food and Drugs Act is concerned—is Solicitor McCabe. By framing and manipulating the departmental rules with all the skill of a pettifogging lawyer, he has put himself in a position of being sole judge whether cases against food "dopers" and "patent-medicine" fakers should or should not be prosecuted. Dr. Wiley's bureau investigates cases of food adulteration and drug misbranding, carefully and scientifically examines the products and submits evidence to show that certain foods or drugs are adulterated or misbranded. Mr. McCabe, by the autocratic use of powers that he has delegated to himself, may bury in the government files all the evidence submitted. That he has thus withheld from the courts evidence of violations of the law has been shown at the present congressional investigation.

It is not surprising that a man who could thus "protect" manufacturers who might have been proved guilty, should have altered the court's decrees when such decrees brought out facts regarding sodium benzoate that were distasteful to him and the "interests" he serves. The exercise of this autocratic power, which has long been known to those who were conversant with the inner workings of the Department of Agriculture, may explain why the New Hartford Canning Company, of which Vice-President Sherman is the reported head, was not prosecuted for selling short-weight products even though evidence to that effect had been collected by Dr. Wiley's assistants. It may also explain why the cases against the Duffy Malt Whiskey fraud, Kilmer's Swamp Root and scores of other similar preparations have never been brought to the courts.

The American people, after having fought for over seventeen years to get the Food and Drugs Act on the federal statute books, finally succeeded—thanks largely to the aggressiveness and honesty of the chief of the Bureau of Chemistry. That act, although not so strong or comprehensive as it might be, can still furnish a large degree of protection to the public. At the outset the chief of the Bureau of Chemistry tried vigorously and unflinchingly to enforce it. Such enforcement against vested wrongs and opulent dishonesty was distasteful to those in high places. The fortunes that might be made by polluting the food-supplies of the country and by the manufacture of "patent-medicines" were not to be abandoned without a struggle. Pressure was brought time and again to secure Dr. Wiley's removal, but in each case it was found that that official was too strongly entrenched in the hearts of the great American public to be removed on any mere trumped up charge. When the present charges were made against Dr. Wiley, the public and the press showed that they had confidence in him The investigation that was demanded, and that [illegible] being carried on, is proving as rapidly as possible [illegible] judgment of the press and of the public is to be [illegible] on. Dr. Wiley will come out of the case stronger and better loved than ever. His traducers, we believe, will be relegated to that political oblivion to which they belong.

PHYSIOMEDICALISM

As will be noticed elsewhere in this issue, the last of the colleges which represented the physiomedical sect has gone out of existence. This sect has endured for three-quarters of a century and was one of the "schools" of medicine which have existed only in this country.

According to its adherents, physiomedicalism was founded in New England early in the last century by Samuel Thomson (1769-1843), a native of New Hampshire. Thomson was a self-educated man, a student of nature, who strongly advocated care of the stomach, good food and proper elimination together with vapor baths and sweating and also employment of certain botanic drugs such as lobelia, marigold and yellowroot. Many of his principles and methods are matters of common sense and, in fact, were not uncommonly employed by other successful physicians. The emphasis which was laid on them in a special book circulated by Thomson, however, no doubt led to the formation of this particular school of medicine and also drew into it a number of very able men, some of whom, from the educational standpoint at least, were destined to have a wider influence than Thomson himself.

Thomson was not altogether unselfish, however, in his efforts to cure the ailments of a suffering humanity. He secured from the government a patent giving him the exclusive use of certai [illegible] licines of which he was recognized as the origi [illegible] Thereupon he began a systematic monoj [illegible] selfishness than his friends were pre[illegible] small books outlining his principles and methods of treatment were sold for twenty dollars, including a written permit to one family to use his medicines. Agencies were established in all the principal cities and so-called botanic societies, made of holders of permits, organized. The income from this business must have been enormous. One agent alone in about three years' time is said to have collected about $80,000. Although enabled for many years by his patent rights to control this profitable enterprise, in time infringements became numerous and the latter part of Thomson's life was largely spent in contentions with his agents.

Although Thomson is recognized as the founder of physiomedicalism, he really opposed the formation of colleges. Dr. Alvin Curtis, who organized the first physiomedical college in 1838, had aroused Thomson's enmity by advocating a more thorough medical education. The first college was located at Columbus, Ohio, but was removed to Cincinnati, in 1841, where it continued under varying fortunes until about 1880. Other colleges known as "Thomsonian," "botanico-medical," or "physiomedical" colleges were organized later in Georgia, Massachusetts, Illinois, Indiana and Texas. So far as it is known no colleges were organized outside of the United States. Only about twelve colleges altogether were organized, omitting a fraudulent concern which was organized in Oklahoma, and only three or four were existing at any one time. Only three have been in existence since 1900, one each in Illinois, Indiana and Texas.

Medicine of to-day is more largely based on scientific facts and there is less room for the differences of opinion which in earlier times led to the formation of medical sects. Formerly valuable principles in the treatment of disease may have needed the emphasis which medical sects laid on them, but not so to-day In this day of the microscope, the special laboratory test, of full-time instructor and of medical research, all methods will be put to the test, the good will be utilized and the useless will be discarded. Sectarianism, dissension and doubt must give way to scientific facts and to certainty.

SEVEN YEARS' PROGRESS IN MEDICAL EDUCATION

Those who have been watching the development of medical education in this country have noted with no little astonishment and gratification the remarkable progress that has been made in recent years and particularly since the American Medical Association created its permanent committee, the Council on Medical Education. At the beginning of its work in 1905, after a thorough investigation of conditions, the Council formulated two standards of medical education, one for immediate adoption and an ideal standard for future consideration. These standards were not for any one state or for any one section, but for the entire country. The result is that nearly all colleges are up to or beyond the standard recommended in 1905 for "immediate adoption," while more than a third of the colleges (42) have, so far as entrance requirements are concerned, adopted the "ideal," namely, a four-year high school education, plus at least one year to include thorough courses in physics, chemistry, biology and modern languages.

During 1906 and 1907, the Council made the first complete personal tour of inspection of the medical colleges of the United States that had ever been made, and in 1907, reported its findings at its annual conference and to the House of Delegates of the American Medical Association. This inspection revealed the fact that nearly a third of the medical schools existing at that time were seriously defective in their methods, standards and equipment. Since that report was made the decrease in the number of these inferior colleges has been marked, while on the other hand, there has begun a corresponding improvement in many other colleges. The second inspection was completed in 1910, and resulted in the publication of a classified list of medical colleges. This doubtless gave added impetus to the improvements being made and to the further elimination of unworthy colleges. In seven years, therefore, the over-supply of medical schools has been reduced in number, quantity giving way to quality, and a decided check has been placed on the rapid multiplication of inferior schools.

In 1908 and 1909, a thorough study of the medical college curriculum was made by a special committee of the Council, made up of over a hundred leading medical educators, to ascertain the relative value of the subjects of the curriculum in order that proper emphasis might be laid on them in the medical course. This special study also included the character of equipment, methods of instruction, qualifications of teachers, necessary hospital facilities, etc. As a result of this and the Council's reports based on its actual inspection, an unprecedented improvement in the physical equipment and methods of medical education was started. New college buildings have been erected; more teaching hospitals have been secured; new laboratories have been equipped and more expert full-time teachers employed.

During each of the seven years the Council has held a special, delegated conference attended largely by members of state licensing boards, university presidents, representatives of medical colleges and other prominent educators. These conferences have had a wide and powerful influence in the progress that has been made. They have resulted in more uniformity of effort on the part of all forces working for the betterment of educational standards and have provided opportunity for the study and discussion of educational problems. Above all, however, at these conferences, the attention of university presidents and others has been drawn to the absolute necessity of state aid or private endowment for medical schools. As a direct or indirect result of this campaign, the amount of money given for medical education has increased from a few thousands of dollars during 1904 to several millions of dollars during the last year. This is indeed encouraging and gives promise of even greater advancement in the immediate future.

Of course, not all the credit for these vast improvements belongs to the Council on Medical Education. Nevertheless this body, representing the organized profession of the country and holding up standards of national and not sectional scope, was bound to have a powerful influence. It has cooperated with the other agencies which have been doing masterly work in their various fields, and has brought about greater harmony and more unanimity of effort. These achievements are the more gratifying since all the agencies save one, the Carnegie Foundation for the Advancement of Teaching, are entirely made up of physicians and fully represent the medical profession. Meanwhile, no one is better acquainted with the needs of the people in regard to the prevention and cure of disease and the preservation of health and healthful conditions than the medical profession itself. And that the medical profession may be even more capable of caring for these needs, nothing is more important than the continued improvement of medical education.

Current Comment

RADIO-ACTIVE MENTHOL-IODIN OR DIORADIN

Another consumption cure! This time it is one of the semi-ethical, quasi-respectable type brought out by a European physician, delivered to the world *via* sensational newspaper articles in which the "chemical name" of the preparation is emphasized and the proprietary name kept in the background. The latest panacea is marketed under the proprietary name Dioradin and is described by its "discoverer" as "radio-active menthol-iodin." Professor de Szendeffy of Budapest is the originator of the new "specific"; Drs. Samuel Bernheim and Louis Dieupart of Paris seem to have been the ones selected by Professor de Szendeffy to deliver the news of the wonderful discovery to the public—and incidentally to the profession. Dioradin comes in boxes of six ampoules, price $3.60. It is administered intramuscularly. Its composition, as described both in the American newspapers and in the European medical journals, is said to be:

Peptonized iodin	0.75 cg.
Menthol	0.06 cg.
Radium-barium chlorid in ethereal solution	1/10 drop

Of course, what peptonized iodin is, no one but the inventor of Dioradin seems to know. Radium-barium chlorid may be a definite product, but there is a delightful vagueness regarding the strength of the "ethereal solution" that is employed. The same vagueness is found in the description of cases in which the "cure" has been tried. Glittering generalities abound and, while these make interesting newspaper reading, they are very unsatisfying to the physician who would like definite, scientific evidence. Possibly Professor de Szendeffy has a remedy that may prove of moderate value in the treatment of tuberculosis; if so, it is unfortunate both for the public and for scientific medicine that it has been introduced by such crude methods. As the London *Lancet* says, in summing up the case against this much-vaunted remedy: "The exploitation in the lay press of immature work in regard to any medical question is particularly to be deprecated. Hopes are raised in the minds of many sufferers which are fore-doomed to disappointment, more especially when they rest on such slender foundation as the treatment here suggested."

THERE'S A REASON

Our readers will remember that when the manufacturer of Postum Cereal and Grape-Nuts was forced to show his hand, it developed that the only "famous physician" whose name was signed to a Postum testimonial "turned out to be a poor old broken-down homeopath, who is now working in a printer's establishment," and who received $10 for his testimonial. These facts came as a surprise to those who are familiar with the testimonial business. When one considers how easy it is to get physicians of a certain class to write testimonials for any food or medicine bearing a proprietary name, it seems strange that Mr. Post should have had such a poor collection. Since the trial, at which these facts were brought out, this enterprising breakfast-food manufacturer has been endeavoring, apparently, to remedy the deficiency that existed in his advertising department. Unsigned testimonials from physicians are being published, the names and addresses to be furnished on application. How such testimonials are obtained, we do not know. A possible explanation has been suggested by physicians who have sent in some letters to The Journal. These letters consist of personal communications from the *American Journal of Clinical Medicine (née Alkaloidal Clinic)* to physicians over the country and read as follows:

> *Dear Doctor:* The advertising of Postum and Grape-Nuts has been appearing in *Clinical Medicine* for the past ten years. We have always believed in the purity of these products. In fact, we have used them ourselves and have recommended them extensively.
>
> Will you cooperate to the extent of giving us your opinion of these products? Have you used them personally and have you recommended them to your patients, and with what results?
>
> Your reply, using the stamped return envelope enclosed, will be appreciated.
>
> Yours sincerely,
> The American Journal of Clinical Medicine.

A study of the wording of this letter makes it plain that only those physicians who hold the same favorable opinions regarding Grape-Nuts and Postum that are held by the *American Journal of Clinical Medicine* will be likely to answer this ingenuous appeal. Such testimony, of course, will please not only Mr. Post, but those publications that wish some excuse for participating in the benefits of his million-dollar advertising campaign. Six years ago The Journal showed that Duffy's Malt Whiskey was being advertised by means of fraudulent testimonials. Since that time the Duffy concern has worked up a nice line of bona fide testimonials from not-too-particular physicians. The task, apparently, was neither difficult nor expensive. History is about to repeat itself, it seems, in the case of Postum and Grape-Nuts. The spectacle is not a pretty one and is somewhat disheartening to those who would believe that the medical profession is becoming more cultured and scientific. We hesitate to believe that, in his search for testimonials, Mr. Post felt impelled to enlist the help of that particular journal. While to collect such testimony through such an instrumentality may be perfectly logical, the ease with which it may be otherwise obtained makes it quite unnecessary.

DR. FRANK P. FOSTER

Our obituary columns this week contain the announcement of the death of Dr. Frank P. Foster, for over thirty years editor of the *New York Medical Journal.* Dr. Foster, since the death of Dr. George F. Schrady a few years ago, has been recognized as the dean of the medical editors of this country. Dr. Foster's energies were varied, but especially literary in character. Aside from his contributions to the periodical of which he was editor, he has written several books, and has contributed to many others. As a monument of his literary labors may be mentioned the "Encyclopedic Medical Dictionary" which bears his name, a four-volume book that has been translated into seven different languages. Dr. Foster was a moral and intellectual force in medical literature. Until recently he took an active interest in all that related to medicine, and his influence was always in the right direction. His friends count it a privilege to recall his fine character, his charitable judgment, his facile pen and his ever-ready assistance so freely given from his great store of knowledge.

AMERICAN MEDICAL DIRECTORY—THIRD EDITION

In this week's Journal appears an insert announcement of the third edition of the American Medical Directory, now in course of preparation. Since the publication of the second edition in the fall of 1909, a large amount of additional data has been secured regarding medical schools, hospitals and public institutions, professional organizations and especially regarding physicians themselves. The material which was obtained for the two previous editions has been carefully revised and corrected. The work which has been done insures a third edition which will be fuller, more complete and more accurate than either of the preceding editions. Based on the only firm foundation which we have in this country, viz., the records of the state licensing boards and the alumni lists of medical colleges, making no distinction between classes of physicians so far as information is concerned and containing three times as much data as any other medical directory published, the American Medical Directory is recognized as the standard official authoritative directory of the medical profession of the United States and Canada. It is the only national directory published as a non-commercial enterprise and must be issued for some time to come at a financial loss. Much expense has been incurred by the Association in getting the fundamental data covering especially the school of graduation and license. The publication of such a reference book is of direct interest and value to every American physician, medical college and hospital. We earnestly bespeak for this very important work the support of every member of our profession. It is hoped that each physician who is asked to assist in furnishing information will respond willingly and promptly. By united effort and cooperation it will be possible to make this publication a realization of the ideal for the attainment of which it was inaugurated, namely, an official and accurate roster of the American medical profession.

LESLIE'S WEEKLY—A CONSISTENT JOURNAL

The clipping bureau service of the American Medical Association is a most complete one. We receive, daily, hundreds of clippings from the various newspapers all over the country. Since the abortive attempt of Messrs. Wickersham, McCabe and Dunlap to oust Dr. Wiley has become public property, we have received newspaper items on the subject literally by the thousand. The unanimity with which the press of the United States has supported Dr. Wiley in his present fight is a surprise even to those who know how well the chief of the Bureau of Chemistry deserves such support. Among the one or two news items and editorial comments that show their writers to be unfriendly to Dr. Wiley and antagonistic to his work, one appeared in *Leslie's Weekly*, which expresses itself in part as follows:

> "Dr. Wiley is not the author of the pure-food law. It would continue to be enforced whether he were in the public service or not. He has occupied a subordinate place in the department, but has always managed to make it appear that he was the only champion of pure food at Washington. The public may rest assured that the pure-food law will be enforced just as vigorously and earnestly whether Wiley stays or goes."

This editorial statement is one that those who are familiar with *Leslie's Weekly* would logically expect to find in that publication. The antagonism of some journals is to be desired rather than their approbation; *Leslie's* is one of them. For years there have appeared at intervals speciously written "special articles" in this publication, devoted to the exploitation of "patent medicines" and quackery. Oren Oneal, the eye quack of Chicago, the wide-spread fake Viavi, and the Alexander cancer cure—each of these in turn has been the subject of fulsomely laudatory articles appearing in *Leslie's Weekly*. Under the circumstances, it is evident that this journal's antagonism to Dr. Wiley is one more point in that gentleman's favor. Had it expressed itself in the same terms of warm commendation that have characterized the editorial expressions throughout the country generally, it would have been a grave embarrassment to the chief of the Bureau of Chemistry. In the estimation of the public, one of Dr. Wiley's greatest assets is the character of the enemies he has made. The opposition of the food dopers and the "patent-medicine" makers has long been known; *Leslie's* having lined itself up with its logical associates, the public will find one more reason for upholding Dr. Wiley.

INTERESTING DETAILS COMING

The investigation by a congressional committee of the charges against Dr. Wiley is bringing out some interesting details. When the hearing is over, we shall probably publish such part of the evidence as will prove of value to physicians.

EDUCATIONAL PROGRESS IN GEORGIA

By recent legislation the Medical College of Georgia, located at Augusta, has been made an integral part of the University of Georgia. The people of Augusta had already awakened to the needs of its medical school and had raised $46,000 by subscription for its equipment. The city of Augusta has agreed to erect a new city hospital at a cost of $200,000 on the campus of the medical school and has further agreed to place it under the perpetual and unrestricted control of the medical faculty as a teaching hospital. It was doubtless this energetic action by the city and people of Augusta which won for them favorable action by the Georgia legislature. It is to be hoped that this action creating a state-supported medical school will lead also to the securing of better legal standards of medical education and licensure in that state. Georgia cannot well afford to assume the responsibility of furnishing a good training for those who are to have in charge the lives and health of the people of that commonwealth, and at the same time leave the people unprotected against the ignorant and poorly trained graduates of low grade colleges of that and other states.

Medical News

ARKANSAS

Society to be Organized.—The North Arkansas Four Counties Medical Society is to be organized at a meeting to be held at Hardy, September 6 and 7, under the auspices of the Sharp County Medical Society.

Railway Surgeons Meet.—At the semi-annual meeting of the surgeons of the Missouri and North Arkansas Railroad, Dr. Hugh L. Routh, Batavia, was elected president, and Searcy was selected as the next place of meeting.

Personal.—Dr. William T. McCurry, Texarkana, with his wife and daughter, sail for Europe next week.——Dr. A. G. Thompson, Pine Bluff, physician for the Sawyer and Austin Lumber Co., has resigned, to take effect September 1.——Dr. Monroe D. McClain, Little Rock, has been elected state physician of the Modern Woodmen of America.

Typhoid in Little Rock.—Surgeon W. H. Frost, Public Health and Marine-Hospital Service, who has been making an investigation of the typhoid situation in Little Rock, reports that while it is true that Little Rock has suffered during the last two months from an epidemic of typhoid fever, there is no need for alarm in this regard in the city as the number of cases is steadily on the decline.

CALIFORNIA

Branch Society Meets.—At the annual meeting of the Santa Monica Branch of the Los Angeles County Medical Association, Dr. John A. Balsley, Santa Monica, was elected president; Dr. H. Wilson Levengood, Ocean Park, vice-president, and Dr. George A. Fielding, Sawtell, secretary-treasurer.

Medical Society Condemns Lodge Practice.—The Santa Clara County Medical Society, at its annual meeting, July 19, is reported to have adopted amendments to its by-laws condemning the practice of members of caring for lodge members on the contract plan. The amendments allow members of the society to care for railroad contract work and work in boarding schools and in charitable institutions.

New Home for Lane Library.—The Lane Library is soon to be housed in a new three-story building to be erected on the corner of Sacramento and Webster Streets, San Francisco, at a cost of $100,000. The building will be ready for occupancy at the end of the school year and will accommodate the Lane Medical Library which was founded by Dr. Lane, former president of Cooper Medical College, and the medical library of Leland Stanford University.

COLORADO

No Public Drinking Cups.—The law prohibiting common drinking cups in public places is now in effect in Colorado.

Bubbling fountains have in many places taken the place of the cups.

New Hospital Wing Opened.—The new wing of the Denver County Hospital has been formally opened. The building has cost $120,000 and will accommodate eighty patients, and contains a laboratory, maternity wards, children's wards and operating rooms.

State Dairy Law.—The new state dairy law forbids the handling of milk in storerooms where oil, poultry or vegetables are kept. Preservatives are barred. The dealer with one cow, selling milk to his neighbor is under the same regulations as the large dairyman and must obtain a license. Milk cans are not allowed to stand at railroad stations for more than one day.

Health Train for Colorado.—The State Board of Health has announced its intention of adopting the method used by the Louisiana State Board of Health for the promulgation of information regarding health and sanitation and expects to start a special health train on a tour of Colorado about January 1. During the tour, which is to be educational, demonstrations regarding pure food, health and sanitary matters will be made, lectures will be delivered and literature will be distributed.

GEORGIA

Open-Air School Established.—The first open-air school to be established in the South will be opened in Atlanta next month under the auspices of the Ninth Avenue Presbyterian Church.

City Hospital Planned.—A movement has been inaugurated by the citizens of Dublin for the establishment of a hospital in that city. James M. Finn has been appointed chairman and R. M. Martin, secretary of the committee on the hospital enterprise.

District Meeting.—At the annual meeting of the First District Medical Society held at Atlanta, August 7, the following officers were elected: president, Dr. Edward T. Coleman, Greymont; vice-presidents, Drs. Lorin V. Strickland, Cobbtown, and John W. Daniel, Savannah; and secretary-treasurer, Dr. John M. Sigman, Savannah.

Medical College Directors Named.—The governor has appointed the following directors of the Medical College of Georgia, Augusta: Hon. A. L. Miller, Macon; Hon. Enoch H. Calloway, Augusta; Hon. John T. West, Thomson, and Hon. William A. Lattimer, Augusta, for two years, and Hon. P. A. Stovall, Savannah, and Hon. L. C. Hayne, Augusta, for six years from August 3, 1911.

Medical Scholarships Announced.—Scholarships in the Medical College of Georgia, Augusta, have been bestowed on twenty-six young Georgians by the governor as follows: first district—D. C. Colson, Sylvania, Screven County; Gordon Herrington, Nunez, Emanuel. Second district—T. P. Brown, Beachton, Grady; E. M. Walker, Tifton, Tift. Third district—W. B. Watts, Jr., Byromville, Dooly; C. C. Frederick, Wellston, Houston. Fourth district—Arthur H. Drane, Buena Vista, Marion; J. C. Bonner, Carrollton, Carroll. Fifth district—Nathan G. Rice, Atlanta, Fulton; J. C. Savage, Jr., Atlanta, Fulton. Sixth district—Linn C. McAfee, Macon, Bibb; B. W. Freene, Haddock, Jones. Seventh district—Arthur Horton, Ranger, Gordon; Egbert M. Townsend, Tilton, Whitfield. Eighth district—Wilbur Gibson Jenkins, Eatonton, Putnam; Earle Newsom, Union Point, Greene. Ninth district—J. W. Wallace, Commerce, Jackson; T. L. Holcombe, Statham, Jackson. Tenth district—William V. Verdery, Harlem, Columbia; John R. Lewis, Sparta, Hancock. Eleventh district—J. C. Carter, Jr., Dublin, Laurens; Warren L. Hall, Nicholls, Coffee; and at large—Robert C. Montgomery, Junction City, Tolbert; J. L. Logue, Louisville, Jefferson; Garnet Edwards, Crawfordville, Taliaferro, and Fred Ware, Wrightsville, Johnson.

ILLINOIS

New Asylum Site.—The State Board of Administration has had drafted the itinerary of a trip to visit the seventy-one sites offered for the new state insane hospital for which $1,500,000 has been appropriated by the legislature.

Hospital Closes.—The Franciscan Sisters' Hospital, Highland, known as St. Joseph's Hospital, closed its doors temporarily, August 9, on account of lack of funds. The Sisters claim that they are obliged to accept a certain percentage of charity patients and that for the county patients the hospital receives only 50 cents a day for the first fifteen days and 20 cents a day thereafter.

The New Cook County Hospital.—Preliminary plans for the new Cook County hospital have been completed by the county architect. The main portion of the new structure, first to be erected, will cost between $2,000,000 and $3,000,000. It will be nine stories high, 950 feet long and 59 feet wide, fronting on Harrison Street, and will accommodate approximately 1,300 patients. On the ninth floor of the building will be seven operating rooms and two amphitheaters, together with the necessary anesthetic and recovery rooms, etc. There will also be four roof-gardens at the disposal of the patients.

Personal.—Dr. John A. Pratt, Aurora, has been appointed oculist for the Aurora division of the Burlington system. ——Dr. James A. Rutledge, Elgin, has been appointed medical director of the Modern Woodmen's Sanatorium, Colorado Springs, and will assume charge about September 1. At present the sanatorium accommodates 180 patients, but when completed the capacity will be 400.——Dr. Elmer E. Nystrom, assistant physician of Peoria County, who has been dangerously ill with an infection of the ear, is convalescent.——Dr. Charles B. Dirks, a member of the staff of the Kankakee State Hospital, has been appointed assistant superintendent of the Elgin State Hospital.——Dr. Charles E. Crawford, Rockford, has been elected grand medical examiner of the Sons of St. George, Illinois jurisdiction.

Chicago

Health Exhibit Goes to Canada.—The Chicago Department of Health has decided to send its health exhibit, in charge of Dr. C. St. Clair Drake, to the Canadian National Exposition which is to be held in Toronto from August 25 to September 11.

Large Employers of Labor Oppose Tuberculosis.—The directors of the Chicago Tuberculosis Institute announce that they are ready, through their advisory committee on factories, to enter into practical cooperation with large employers of labor with a view to weeding out and treating employees suffering from tuberculosis and to the prevention of the spread of the disease among their fellow workers. A start has been made at the plant of the International Harvester Company and two of the largest mail-order houses already have established cottages for the treatment of employees suffering from tuberculosis.

Personal.—Dr. Ralph R. Campbell announces his return to Chicago and resumption of practice.——Dr. and Mrs. Wesley J. Woolston have returned from Europe.——Dr. Harry S. Gradle has been elected professor of ophthalmology in the Chicago Ear, Eye, Nose and Throat College.——Dr. and Mrs. Harry D. Orr have returned from Europe.——Dr. Frank Branen sustained painful injuries, August 6, in a collision between an automobile and a street car.——Dr. Joseph P. Smyth has been elected high chief medical examiner of the Catholic Order of Foresters.——Dr. Alexander Hugh Ferguson is reported to be seriously ill with septicemia due to a carbuncle.

INDIANA

Hospital Enlarged.—The Lutheran Hospital Association, Fort Wayne, has purchased adjoining property, the buildings on which, after remodeling, will be used for a maternity.

Raise Money for Hospital.—At a mass meeting of the citizens of Gary, August 7, $20,000 was raised for the assistance of Mercy Hospital in that city. This amount is needed to complete the new hospital building which will have cost when completed $100,000.

Personal.—The residence on the farm near Noblesville of Dr. Simon P. Scherer, Indianapolis, was burned, August 10.——Dr. Fred E. Jackson, intern at the City Dispensary, Indianapolis, has resigned.——Dr. G. S. Hobbs, intern at the Methodist Episcopal Hospital, Indianapolis, has completed his term of service and commenced practice in that city.——Dr. Lewis Maxwell, Indianapolis, has returned after a year abroad.——Dr. F. W. Hixon has been commissioned first lieutenant, medical corps, Indiana National Guard.——Dr. Jonas Stewart, Anderson, was thrown from his buggy in a runaway accident, August 4, and painfully injured.——Dr. Robert A. Bunch, Muncie, who has been seriously ill, is reported to be convalescent.——Dr. Joseph E. Showalter, Waterloo, has been appointed a member and secretary of the Waterloo school board.

IOWA

New State Journal.—Iowa has been added to the list of states whose medical associations publish journals. The *Journal of the Iowa State Medical Society* made its appearance, July 15, with Dr. David S. Fairchild, Clinton, as editor and Dr. Clyde A. Boice, Washington, as associate editor. The first issue contains a report of the proceedings of the state medical society, the president's address, address on surgery, proceedings of the House of Delegates and a list of officers and directors of the state, district and county societies.

KENTUCKY

Gets Field Hospital Equipment.—The Kentucky State Guard has obtained from the War Department a field hospital equipment and has organized a field hospital with Major Charles W. Hibbitt, Louisville, in command.

New Sanatorium.—Work will be begun shortly under the provisions of the will of the late Dr. John A. Ouchterlony for the construction of a tuberculosis sanatorium on the grounds of the Sisters of Nazareth on the Newberg road about two miles from Louisville.

The State Board and Pellagra.—A special meeting of the State Board of Health was held at Corbin, August 9, to discuss the problem of pellagra, more than 100 cases of which have been reported from Bell and Whitely counties in addition to twenty-four cases reported from the Lexington and Hopkinsville state hospitals for the insane.

Transfer Patients from Hospital.—A contract for moving the inmates and the equipment from the old city hospital, Louisville, to the temporary hospital located in the building of the former Kentucky School of Medicine, will be awarded this week by the board of public safety. The patients suffering from tuberculosis will be moved to the Waverly Hills Sanatorium, as no provision is to be made in the new city hospital for cases of tuberculosis.

Personal.—Dr. Joseph M. Mathews, Louisville, has been appointed a member of the State Board of Health, vice Dr. William Bailey, deceased.——Dr. William A. Quinn, Henderson, has been appointed a member of the State Board of Health to succeed himself.——Dr. Henry Enos Tuley has resigned as professor of obstetrics at the University of Louisville and has been succeeded by Dr. William B. Doherty. Dr. Doherty has also been appointed a member of the State Library Commission.——Dr. Charles J. Lockhart, Owensboro, was seriously injured in a runaway accident, July 14.——Dr. Lee C. Redmon, Lexington, has been elected medical supervisor of the city schools.

LOUISIANA

A Good Record.—The president and secretary of the Caldwell Parish Medical Society announce that every physician in the parish is a member of the society.

Personal.—Dr. Stephen W. Stafford, New Orleans, intern in the Charity Hospital, was operated on in that institution, August 7.——Dr. Louis J. Genella has been appointed superintendent of the scout camp at Clairmont Harbor, vice Dr. Mayer Newhauser.——Dr. James F. Smith, Leesville, is reported to be ill at his old home in Eutaw, Ala.——Dr. William T. O'Reilly, chairman of the State Board of Health, has gone to Nicaragua for a vacation.——Dr. Erastus J. Lyons, Lake Charles, after practicing for fifty years in Calcasieu Parish, has retired from practice.——Dr. Cornelius A. M. Dorrestein has been appointed outdoor clinical assistant in the gynecologic and obstetric department of Touro Infirmary, New Orleans.——Dr. E. C. Samuel has been appointed junior in the department of radiology, and Dr. Abraham L. Levin, outdoor clinical assistant in the gastro-intestinal service of the department of medicine.——Dr. Frazer B. Gurd, junior pathologist of Touro Infirmary, has resigned.——Dr. Marion S. Souchon has been appointed a member of the board on administration of the charity hospital, New Orleans, vice Dr. George S. Bel, resigned.

MARYLAND

Baltimore

Zones of Quiet.—Alderman T. O. Heatwole has prepared an ordinance which will be introduced at the meeting of the city council in September. The ordinance will empower the city engineer to erect signs at intersections of streets in which there are hospitals or sanatoriums, and these will be known as "Hospital Streets." In such localities the ringing of streetcar bells, the playing of street organs, crying of hucksters, etc., are prohibited under a penalty of a fine of $10.00.

Personal.—Dr. Richard C. Massenburg, Towsen, is ill with typhoid fever.——Dr. Robert Hoffman sailed for Germany, August 10.——Dr. Winford H. Smith, new superintendent of the Johns Hopkins Hospital, assumed his duties August 15, succeeding Dr. Henry M. Hurd who had been superintendent of the institution for fifteen years.——Dr. Charles Phillips Emerson, associate professor in medicine in Johns Hopkins University has accepted the deanship of the Indiana University School of Medicine, Indianapolis, vice Dr. Allison Maxwell.

MASSACHUSETTS

New Private Hospital.—A movement has been started in Boston by Drs. Arthur T. Cabot, William T. Councilman, Reginald H. Fitz, Joseph L. Goodale, Francis B. Harrington, Henry Jackson, Robert W. Lovett, John L. Morse, Edward Reynolds, Maurice H. Richardson, Frederick C. Shattuck, Edward W. Taylor, Paul Thorndike and J. Collins Warren to provide hospital facilities for private patients who are able to pay for the service they receive. It is proposed to offer $500,000 worth in stock and as much more in bonds in order to provide the funds necessary for this undertaking.

Officials of Hospitals.—Dr. Maurice H. Richardson has been appointed surgeon-in-chief of the Massachusetts General Hospital with Drs. Francis B. Harrington and Samuel J. Mixter as assistants, with the titles of chiefs-of-service. Dr. George Morse has been placed in supervision of the work of house officers with the title of house surgeon. Dr. Hugh Cabot will be placed in charge of the genito-urinary cases. The outpatient staff has been increased and now includes Drs. Channing C. Simmons, Samuel Robinson, Beth Vincent and John Homans with Drs. John B. Hartwell, Wyman Whittemore, Edward P. Richardson and William J. Mixter as assistants.——Dr. Herbert B. Howard is announced as superintendent, Dr. Harvey Cushing, surgeon-in-chief, and Dr. Henry A. Christian, physician-in-chief of the new Peter Bent Brigham Hospital.

The New Peter Bent Brigham Hospital.—Ground was broken, August 7, for the Peter Bent Brigham Hospital, which will eventually comprise fourteen buildings on Huntington Avenue and Francis Street, next to the Harvard Medical School. The late Peter Bent Brigham bequeathed about $1,000,000 to found a hospital in Boston "for the care of sick persons in indigent circumstances residing in the county of Suffolk." By the contract the buildings are to be complete in fourteen months. They are to be of brick and limestone. The main architectural features will be the administration building and its two flanking structures which will form an amphitheater. There will be five wards which will have their ground level only one low step above the ground. To the westward of the entrance court will be the dispensary building and the general clinical amphitheater, which will be connected by covered corridors with the administration building, the dispensary and the nurses' home. To the northwest of the administration building will be the domestic building in which all the food will be prepared for the hospital staff, nurses and patients, and this building will be connected by a corridor with the main building. Westward from the domestic building comes the surgical, medical and pathological buildings. The superintendent's house will be to the east of the medical building. The wards first to be built will accommodate 240 patients.

MICHIGAN

Bequests.—By the will of the late Henry A. Cleland, Detroit, $5,000 is left to the Children's Free Hospital, Detroit, and $3,000 to the Wayne County Medical Association.

Mason to Have Private Hospital.—A house has been purchased by F. P. Dean which will be remodeled and equipped by Dr. Richard H. Alexander, Dansville, as a private hospital.

Fire Destroys Medical Building.—The western half of the medical building, one of the oldest structures on the campus of the University of Michigan, Ann Arbor, was destroyed, August 12, by fire believed to have been of incendiary origin.

Personal.—Dr. Conrad George, Jr., Ann Arbor, was seriously burned in the face and eyes by splashing of sulphuric acid from the battery of his automobile.——Dr. Andrew T. Sherman, Detroit, has purchased the Anhut Apartments on Trumbull Avenue.

Antituberculosis Society Elects.—The Jackson County Association for the Study and Prevention of Tuberculosis at its regular meeting elected the following officers: president, E. J. Ryerson; vice-president, Dr. Peter Hyndman; secretary, Dr. Harry D. Obert (reelected), and treasurer, Fred Helmar (reelected). After the meeting a board of directors was elected, composed of the officers and enough additional members to make a total of fifty, including representative business men and women of Jackson. A tag or membership day is soon to be held to enlist funds for the erection of a modern sanatorium.

MINNESOTA

Fails to Pass Enabling Act.—Although the state legislature appropriated $500 to be used to defray the expenses of a board to be known as the State Tuberculosis Commission, it failed to pass the necessary enabling act, and as a result the governor has been advised by the attorney general that he has no power to create such a commission with authority to expend the money appropriated.

Personal.—Dr. John E. Corrigan has been appointed health officer and a member of the board of health of Spooner.——Dr. Edward J. Davis, Minneapolis, physician of the Minnesota Old Soldiers' Home, has resigned because of ill health.——Dr. Julian A. DuBois has been appointed physician to the State Home School for Girls, Sauk Centre.——Dr. William H. Hart, Duluth, superintendent of the St. Louis County Sanatorium, has resigned to take charge of the antituberculosis work in Saskatchewan.

Society Merger.—At the joint meeting of the Southern Minnesota and the Minnesota Valley Medical Associations held in Rochester, August 3 and 4, the merger of the societies was perfected and the following officers were elected: president, Dr. Louis A. Fritsche, New Ulm; vice-presidents, Drs. Hugh F. McGaughey, Winona, and John E. Crewe, Rochester; and secretary-treasurer, Dr. William T. Adams, Elgin. One of the features of the evening was the memoir of the late Dr. William W. Mayo, Rochester, presented by Dr. Charles Hill, Pine Island, a physician now in his eighty-fifth year, who forty years ago was associated with Dr. Mayo in St. Paul.

NEBRASKA

Personal.—Dr. Cyrus L. and Leta M. Pickett, formerly of Tecumseh, missionaries of the Christian Church at Laoag, P. I., who have been in the United States for several months, are about to return to the Philippine Islands, sailing from San Francisco, September 3.——Dr. J. H. Stough, Chadron, has recovered from his recent illness.

Typhoid Situation at Beatrice.—An epidemic of typhoid fever is reported to be raging at the Nebraska Institution for Feeble-Minded Youths, Beatrice, where there are twenty-eight cases, including the superintendent and six attendants, with two deaths thus far. Dr. William H. Thomas, Pickrell, the superintendent is reported to be critically ill.

New Hospitals.—The construction of the Omaha Surgical Hospital, which is to be erected for Dr. Albert P. Condon, has been commenced. The building will be 70 by 50 feet, two stories and one-half in height, and will have twenty-three private rooms in addition to two operating rooms, and the necessary sterilizing and etherizing rooms. The building is to cost about $50,000.——The former Holdredge home has been purchased for $50,000 by eight physicians of Omaha, and together with the house next to it will be remodeled as a hospital especially for nervous diseases. The institution will be able to accommodate about forty patients.

NEW JERSEY

Personal.—Dr. Duncan W. Blake, Jr., has been reelected medical inspector of the public schools of Gloucester.——Dr. William G. Schauffler, Lakewood, has been elected president of the new State Board of Education.

Typhoid Epidemic in Clayton.—Because of a serious outbreak of typhoid fever in Clayton, a thorough investigation is being made of every house, with special inspection of drains and sewer. The drinking water of the town is being tested. As soon as the reports come from the laboratory at Trenton, there will be a meeting of the Clayton board of health, the state board and the council of Clayton.

Reorganization of Medical Corps.—The Medical Department of the National Guard of New Jersey has now conformed to the army standard and will henceforth be known as the Medical Corps, N. G., N. J., and the officers will hereafter be designated as officers of the medical corps and will be assigned to the various organizations in the service. The reorganization has been under the direction of Lieut.-Col. Henry Allers, Harrison, assisted by Majors Paul M. Mecray, Camden, and James T. Wyckoff, Leonia. Requisition has been made for a fully equipped field hospital.

NEW YORK

Outing for Medical Staff.—The medical staff of the Syracuse Hospital for Women and Children was entertained by a dinner and outing by Dr. Hersey Goodwin Locke, Syracuse, president of the staff, at his home in Marcellus, July 26.

Cost of State Charities.—The fiscal supervisor of state charities shows in his annual report that the gross expenditures of the institutions reporting to him amount to $2,834,063. The cost of supervising fiscal affairs of institutions was less than 1¼ per cent.

Personal.—Dr. James V. May of Binghamton, has been appointed superintendent of Matteawan State Hospital for the Criminal Insane to succeed Dr. Robert B. Lamb, Fiskill-on-the-Hudson, who recently resigned.——Dr. Frank W. McMorrow, Syracuse, is spending the summer abroad.

Shows Gratitude by Gift.—Mrs. Cyrus H. McCormick, Chicago, has presented the Ithaca Hospital with a new *x*-ray machine at a cost of $500, in appreciation of the careful and prompt attention received at the hospital by her grand-niece, who was injured recently in an automobile accident.

G. A. R. Medical Bureau.—The formation of the Grand Army of the Republic Relief Bureau for the free use of all veterans of the Civil War in the State of New York is announced by Dr. Thomas W. Topham, Brooklyn, medical director of the Department of New York. The personnel of the bureau is as follows: Dr. Lewis S. Pilcher, Brooklyn, surgery; Dr. George Thomas Stevens, New York City, diseases of the eye; Dr. Wendell C. Phillips, diseases of the nose, ear and throat; Dr. Thomas W. Topham, Brooklyn, electrical therapeutics; Dr. J. Bentley Squier, New York City, genito-urinary diseases; Dr. Winfield Ayres, New York City, diseases of the bladder; Dr. Harold Barclay, New York City, diseases of digestion, and Dr. Alcinous B. Jamison, New York City, intestinal diseases.

New York City

Office Building for Physicians.—Plans have been filed for a seven-story building for physicians on West Seventy-Second Street to cost $65,000.

New Hospital.—A charter for a new Lutheran Hospital has been filed with the State Board of Charities and $200,000 has been pledged towards the enterprise.

Health Board to Move.—The city has leased the Abingdon Building, a new building not yet completed, at the corner of Center and Walker Streets, which will be occupied by the Department of Health. The annual rental will be $58,500 and the lease is for ten years.

Mediterranean Liners Held.—The steamers *Calabria* and the *Venezia* which arrived from the Mediterranean on August 11 are being held at quarantine. There was a death from cholera on board the *Venezia* on August 7, while the *Calabria* was held simply as a precautionary measure because she came from Naples.

Bequests to Charity.—The will of the late E. C. Whitney of New York gives $5,000 to endow a bed in the Orthopedic Hospital.——Mrs. Russell Sage has given $5,000 to the building fund of St. Joseph's Hospital at Far Rockaway, N. Y.——The will of the late Simon E. Bernheim leaves $2,500 to Mount Sinai Hospital, Home for Aged and Infirm, and the German Hospital.

Optometry Course at Columbia.—The department of extension teaching of Columbia University announces that it will give a two years' course for optometrists in answer to a special request from the Department of Education of the State of New York. The course is open to anyone who has completed a high school course but does not lead to a degree or a diploma; instead, a report of standing will be submitted to the Board of Regents.

Infant Mortality in New York and Brooklyn.—The Public Service League of Brooklyn has issued a statement based on the reports of the health department, showing that the infant mortality in that borough is greater than in Manhattan. The number of deaths for the last week in July for infants under five years of age was 304, against 284 in New York. At the offices of the health department in Brooklyn it was stated that this discrepancy was probably due to the numerous charitable organizations interested in the care of infants and young children in Manhattan.

Pasteurization Must Safeguard the Milk Supply.—The Commissioner of Health, Dr. Lederle, has made special efforts to ensure a pure milk supply for the city, but admits that it is impossible to exercise a sufficiently rigid inspection of the 44,000 farms in seven states that send 2,000,000 quarts of milk to this city daily. Beginning with January 1, practically all milk for general use must be pasteurized with the exception of the "certified" milk which is known to be produced under exceptional circumstances, and that used only for cooking purposes.

Personal.—Dr. John T. Fitzgerald, formerly medical superintendent of Public Charities in Brooklyn, has been made general superintendent of the Public Charities Commission Hospitals.——Drs. Henry B. Minton, Brooklyn, Dr. Hubbard W.

Mitchell and Dr. Henry W. Frauenthal have sailed for Europe. ——Dr. George G. Rambaud, physician of the Pasteur Institute, who was recently injured in an automobile accident and has been seriously ill in the Vassar Hospital, Poughkeepsie, is now said to be out of danger.——Dr. and Mrs. Ernest P. Livingston sail for Europe, August 12.——Dr. Hugh S. Reed, a physician in the employ of the Department of Health, was struck by a subway train at Fourteenth Street, July 28, and suffered a fracture of the skull.

Aid for Many Charities.—The will of the late John Curley of Brooklyn makes bequests to about fifty charities, among which are: the Sisters of the Poor of St. Francis, in charge of St. Peter's Hospital, $15,000; the Hospital of the Holy Family, $5,000; St. Mary's Hospital, $5,000; St. Catherine's Hospital Association, $10,000; Seney Hospital, Brooklyn Hospital, Brooklyn Bureau of Charities and Long Island College Hospital, each receives $1,000.——The will of Smith Ely, former mayor of New York, leaves about $1,000,000 to charities. Among the charities remembered are the Fresh Air Home for Crippled Children at Sea Breeze, Coney Island, $50,000; West Side Day Nursery of the City of New York, $10,000. After all debts and legacies have been paid, the Children's Aid Society and the New York Society for Improving the Condition of the Poor are to receive $100,000 each on condition that with the sum special endowments be instituted to be known forever as the Ambrose K. Ely Memorial.

OHIO

Personal.—Dr. James J. McClellan, Columbus, who has been seriously ill with septicemia, is reported to be improving.——Dr. Asa H. Syler, Sugar Creek, is ill with typhoid fever.

Secretary of State Board Resigns.——Dr. Charles O. Probst, Columbus, secretary of the Ohio State Board of Health for twenty-five years, has resigned, to take effect September 30.

Gift to Hospital.—Dr. David J. Merriman, Painesville, has donated his medical library together with the cases which contain it to the Painesville Hospital for the use of nurses in training and others who may desire to consult it.

Cincinnati

Personal.—Dr. John D. Miller has been appointed to succeed himself as a member of the board of health.——Dr. Rufus B. Hall is reported to be seriously ill in Cleveland.

PENNSYLVANIA

Personal.—Dr. Edgar Sturge, Scranton, was thrown from his carriage in a runaway accident, August 5, and sustained serious spinal injuries.——Dr. Percy O. Hoskins, West Chester, was operated on for appendicitis in the West Chester Hospital, August 1, and is reported to be doing well.

State Insane Hospital.—Bids were opened on August 8, by the Pennsylvania Commission to erect a state hospital for the criminal insane, for the construction of new buildings known as dining room building, kitchen, bakery, laundry, power building, icehouse, reservoir, system of sewage disposal, together with equipments pertaining to the State Hospital for the Criminal Insane, at Fairview.

Department Aids Country Doctor.—The department of health of Pennsylvania is doing great work for country practitioners. It not only furnishes laboratory facilities for the diagnosis of certain morbid conditions and the detection of obscure sources of disease, but has also put at command of physicians 350 stations at which diphtheria antitoxin may be obtained, and more recently, has established sixty-seven stations at which antitetanic serum may be furnished for indigent patients. The department also supplies physicians with instructions for families detailing the necessary precautions to be exercised by those in care of patients suffering from communicable diseases.

Pure Food Prosecutions Begun.—As a result of the violation of the pure food laws of the state, Dairy and Food Commissioner Foust ordered 215 prosecutions of which 138 are for the sale of milk having a lower quantity of butter fats than the law requires, fifty-three for the sale of cream below state standards and three for the sale of skimmed milk without notice that it was skimmed. These suits will be entered in Allegheny, Armstrong, Beaver, Blair, Butler, Cambria, Center, Chester, Clinton, Dauphin, Erie, Fayette, Huntingdon, Lancaster, Lebanon, Luzerne, Lycoming, McKean, Montgomery, Montour, Northumberland, Philadelphia, Venango, Warren, Washington, Westmoreland, Wyoming and York counties. Seven suits for the sale of ice cream not in accordance with state laws, five for the sale of adulterated non-alcoholic drinks and seven for the sale of adulterated candies, catsup and sausage were ordered in western counties and two suits for the sale of butter against state laws and one for the sale of bad eggs were ordered in Philadelphia.

Philadelphia

Hospital Buys New Quarters.—The American Oncologic Hospital has purchased the large stone residence at Thirty-Third and Powelton Avenue for $40,000, and will at once occupy the property.

Personal.—Dr. John K. Mitchell and Dr. Ernest LaPlace have sailed for Europe.——Dr. William C. Hollopeter has gone to Honolulu.——Dr. William E. Lee, chief visiting surgeon at the Pennsylvania Hospital, has been taken to that institution suffering with typhoid fever.——Dr. L. Webster Fox sailed for Europe, August 3.

Inspection of Public Baths.—Dr. Joseph S. Neff, director of Public Health and Charities, recently ordered a special investigation of swimming pools by a corps of medical inspectors, with the result that many of them, including some prominent club swimming pools were condemned as unsanitary. The investigations embraced twenty-nine swimming pools, of which twenty-two were municipal baths. Ten of these were declared to be in bad condition and improvements were ordered.

To Endow Room in Jewish Hospital.—At a meeting of the officers of the Jewish Hospital Association the offer of Mr. Isaac Wolf, Jr., who stated that he had made a provision in his will for the payment to the Jewish Hospital of $10,000 to endow a room in memory of his parents and to give a donation of $500 yearly during his lifetime, provided that the room were established at once. If for any reason the annual payments of $500 should not be regularly made or if the bequest of $10,000 was not paid under the will such endowment room should cease.

Tuberculosis Pier Successful.—The day camp for consumptives, established on the Bainbridge Street Pier, is now able to care for thirty patients daily. It is open from 9 a. m. to 6 p. m. Luncheons of milk, bread and butter are served at 10 a. m. and 4 p. m. and a good dinner at 12:30. A canvas pavilion, 30 by 40 feet, open on all sides protects the patients from sun, and there are curtains which can be lowered. The two dozen cure-all chairs were loaned by the Shut-In Society, while department stores and other firms have given the furniture needed. The pier is under the care of Dr. Albert P. Francine of the State Tuberculosis Dispensary assisted by a corps of physicians.

Bequest.—By the will of Meyer Seidenbach, $4,000 is devised to charity with the provision that in the event of the death of his widow and children and issue of the latter the trust funds established for their benefit also should go to charity. The will bequeaths to the Jewish Foster Home and Orphanage, $1,000; to the Jewish Hospital Association, $1,000; to the Federation of Jewish Charities of Philadelphia, $1,000; to the German Hospital, $500, and to a Jewish Synagog, $500.

SOUTH CAROLINA

Free Typhoid Serum.—The State Board of Health announces that in addition to the immunizing treatment of rabies, smallpox vaccine and antitoxin for diphtheria, it has decided to begin the free distribution of anti-typhoid serum.

TENNESSEE

College Building Sold.—The building on Broadway, Nashville, formerly occupied by the Medical Department of the University of Tennessee and for the last two years by the Tennessee Hospital has been sold on account of the removal of the medical department of the university to Memphis.

The Pellagra Board.—The board of inspectors of pellagra appointed by the State Board of Health has been completed by the appointment of Dr. Byrd S. Rhea, Bon Air, for the middle division. The three inspectors have taken a ten days' preparatory course in Nashville before entering on their duties. They are to lecture on pellagra in the various counties, and after the lectures, are to accompany physicians in visits to pellagra cases or pellagra suspects, giving personal instruction in each case as to diagnosis, isolation, etc.

VIRGINIA

Memorial Antituberculosis League.—The Latane Antituberculosis League, Winchester, organized as a memorial to the late Dr. Samuel P. Latane, has employed Miss Anne Carson, Riverton, to take charge of its work in Winchester.

Personal.—Dr. Washington B. Sager, Woodstock, has been appointed resident physician at the Alleghany Hospital, Davis, W. Va.——Dr. Robert F. Williams, Richmond, has been selected as dean of the medical school of the state university of Oklahoma, Norman.

Elections.—The Augusta County Medical Association, whose membership includes physicians of Augusta, Bath and Highland Counties, held its annual meeting at Staunton, August 2, and the following officers were elected: president, Dr. Harry F. White, Fishersville; vice-presidents, Drs. Walter S. Whitmore, Mount Sidney; Herman Welland, Middlebrook, and Kenneth Bradford, Staunton; secretary, Dr. Alexander J. Burkeholder, Mount Sidney; treasurer, Dr. Walter F. Hartman, Swoope; censor, Dr. Marshall P. Jones, Churchville; and trustee, Dr. R. Sumpter Griffith, Basic City.——At the annual meeting of the Piedmont Medical Society, held in Charlottesville, July 30, the following officers were elected: president, Dr. George W. Stark, Overton; vice-presidents, Drs. Ernest D. Davis, Standardsville, and Harry W. Porter, Louisa; secretary, Dr. Frank G. Scott, Orange; treasurer, Dr. John T. Walker, Barboursville.

WISCONSIN

Ill and Injured.—Dr. Guy A. Grafton, Hayward, sustained a fracture of the leg and other serious injuries in an automobile accident, August 3.——Dr. William P. Salbreiter, Racine, is reported to be seriously ill with pneumonia.——Dr. Frederick J. Hamlin, Beloit, has gone to South Dakota for a two months' vacation on account of ill health.

Personal.—Dr. Glenford L. Bellis, Antigo, has been appointed a member of the advisory board of the state tuberculosis sanatorium.——Dr. Jonas R. Longley, Fond du Lac, has been appointed local physician for the Soo line.——Dr. Lewis F. Bennett, after twenty-two years' practice in Beloit, has decided to locate in Spokane, Wash. At a farewell banquet given Dr. Bennett by the medical profession and the school board of Beloit, glowing tributes were paid to Dr. Bennett for his work in the civic uplift of the city.

GENERAL NEWS

Soo Line Surgeons to Meet.—The fifth annual meeting of the Minneapolis, St. Paul and Sault Ste. Marie Railway Surgical Association will be held in the Blackstone Hotel, Chicago, October 16 and 17, under the presidency of Dr. Albert E. Halstead, Chicago.

Military Surgeons' Meeting.—The annual convention of the Association of Military Surgeons of the United States will be held in Milwaukee, September 26 to 29. The headquarters will be at the Hotel Pfister and Dr. Gilbert E. Seaman is chairman of the committee on arrangements.

Antismokers Incorporate.—An organization called the Non-Smokers' Protective League of America, having its principal office in New York City, has recently filed papers of incorporation with the secretary of this state. The object of the league will be to enforce laws, ordinances and regulations restricting smoking. Among the directors are Dr. Harvey W. Wiley of Washington, Chancellor James R. Day of Syracuse University, Dr Burt G. Wilder of Cornell University, President David Starr Jordan of Leland Stanford University, Dr. Winfield S. Hall of Northwestern University and other prominent educators.

Wall Charts on Hookworm Disease and Soil Pollution.—The United States Public Health and Marine-Hospital Service has just issued a series of nine wall charts illustrating the anatomy and life-history of hookworms, the methods of their dissemination, methods of prevention, and pictures of severely infected patients. These charts are intended for use in schools, colleges and field work. They are now being used by some of the state boards of health in the campaign for the eradication of hookworm disease. The charts are printed on heavy paper mounted on linen, with wooden hangers and are sold by the Superintendent of Documents, Government Printing Office, Washington, D. C., at $3.00 per set.

Municipal Congress.—The International Municipal Congress and Exposition is to be held at the Coliseum, Chicago, September 18 to 30, inclusive. The purpose of the congress is to discuss municipal problems. Many of the cities of the United States have already designated delegates and the most of these have included representatives from their departments of health. Discussions will be held before the general body by health officers on the "Milk Supply," and the "Advantage of a Low Death-Rate to a City." From September 28 to 30, inclusive, there will be a series of seven meetings participated in by health officers. These are for the purpose of adopting means of controlling such important activities of a city as "The Control of Contagion," "The Control of Milk and Water," "The Disposal of Sewage and Garbage," and methods of supervising those things in a city which easily become a nuisance. The plan is to have the subjects discussed in a very concrete way and then to have those in attendance go on record as in favor of certain methods of procedure, and against other methods. Many of the leading sanitarians of this country have agreed to act as leaders of discussions.

CANADA

Cocain Arrests.—The annual report of the chief of police of Montreal states that since July 1, 1910, there have been more than 150 arrests for either selling or using cocain in that city.

Council Meeting.—The Ontario Medical Council at its July meeting decided to cut out all examinations except the finals and to accept the examinations for the primary and scientific subjects of the provincial universities. The names of two physicians were struck from the register and two were readmitted, one of whom had had his license canceled sixteen years ago. Two representatives of defunct medical teaching boards who were on the staff of the medical department of the University of Toronto were refused status as members of the Council.

Personal.—Dr. Alfred Poole, house physician of the Vancouver (B. C.) General Hospital, has resigned.——Drs. H. H. Manseau, Montreal, Charles A. Hodgetts, Toronto, and Major Loren Drum, Quebec, chief sanitary officer of the Canadian Army Medical Service, have sailed for Europe.——Dr. Richard A. Reeve, Toronto, has been given an honorary degree by the University of Birmingham, England.——Dr. Harry B. Anderson, Toronto, has returned home after a several months' stay in Germany.——Dr. Andrew McPhail, Montreal, editor of the *Canadian Medical Association Journal*, who recently suffered severe injuries to the eyes, is reported to be improving.——Dr. Thomas G. Roddick, Montreal, has recovered from his recent illness.——Dr. Francis J. Shepherd, Montreal, has been reappointed dean of the medical faculty of McGill University.

LONDON LETTER

(From Our Regular Correspondent)

London, August 5, 1911.

The National Insurance Bill: Victory of the Profession

The unanimity of the profession in the face of what they regard as a great danger to their interests (described in previous letters to The Journal) has been crowned with almost complete victory in parliament, which is probably only the prelude to the complete attainment of all their demands. In the House of Commons, Sir P. Magnus, the member for London University, moved an amendment in accordance with the demand of the profession that persons with an income above $500 be excluded from obtaining medical attendance at contract rates. He pointed out that the profession was absolutely agreed on the point. Persons with incomes between $500 and $800 (the present limit of income above which the bill does not apply) should receive a money grant in lieu of medical attendance. The present system of contract attendance applied to 6,000,000 people and the bill as it stood would bring in 9,000,000 more. Experience had shown that while the contract system might be necessary in some cases it was not the best system for the cure of illness. Moreover, many doctors would be absolutely ruined by the bill as it stood and a great extension of the contract system would injure the status and character of medical practice. At present the doctor was able to combine contract with private practice, but if the contract system were to occupy his whole time the position would be intolerable. His whole time would be occupied and he would have neither leisure nor opportunity to keep abreast of the advances of science. Mr. Lloyd-George, the chancellor of the exchequer, pointed out that in many districts all medical arrangements had long been on contract terms, although in the skilled industries incomes above the proposed limit were earned. On the other hand, there were other industrial districts, such as rural ones, in which the incomes earned were below the proposed limit of $500, but the people were as well off, in consequence of lower cost of living, and the contract system did not prevail. Obviously the amendment would be of no advantage to the doctors practicing here who equally objected to the conversion of private into contract practice. A far better method was to leave the question of wage limit to the local health committee. The amendment was negative without a division. Dr. Addison, lecturer on anatomy at St. Bartholomew's Hospital, then moved an amendment authorizing the local committee to require any person whose income exceeds a limit, to be fixed by them, and to allow any other persons, in lieu of receiving medical benefit, to make their own arrangements and to receive the sum which would otherwise have been expended in providing medical benefit. The amendment had a great advantage of introducing elasticity. It was carried by a large majority. It is thus open to the profession, if they maintain their unity, to insist in each locality on whatever limit of income they prefer. This amendment has the advantage over the rigid one of $500, which was proposed at first, that where circumstances require it a still lower limit can be fixed. The two other demands of the profession—that the administration of medical benefits shall be transferred from the friendly societies to the local health committees and allowing the free choice of doctor were also carried by large majorities. The British Medical Association have decided to place the whole bill before the profession again and to convene another representative meeting to consider it after it has passed through committee in the House of Commons. Many of the friendly society officials are very angry that the control of the doctors is taken out of their hands.

The Radium Institute

The Radium Institute, which was founded at the suggestion of the late King Edward two years ago by two well-known philanthropists, Sir Ernest Cassel and Viscount Iveagh, is now compleded. Paying patients will be treated only in association with and through the introduction of their physician. At the first visit they must either be accompanied by their medical adviser or bring with them his written statement of the case, giving details of the treatment already employed. Physicians are cordially invited to be present during the treatment and to assist in it when practicable. The following fees will be charged: for first consultation at the institute, $10; for treatment when the lesion is situated on the external surface of the body with apparatus containing not more than 50 mg. of radium, $10 per sitting; when containing more than 50 mg., $20; when the lesion is situated in a cavity, e. g., larynx, uterus, urethra, etc., $25 per sitting. Necessitous patients will be admitted to free treatment if certified by their physician to be fit subjects for charity. The diagnosis of the disease from which the patient is suffering must rest with the physician introducing him and should the medical superintendent not agree with the diagnosis he will discuss the matter with the physician. Should a third opinion be considered necessary one of the honorary consulting staff will be called in in the case of a free patient. In the case of a paying patient the physician will nominate the consultant, or if he prefers it, leave this to the medical superintendent. In no case will the medical superintendent acting on behalf of the institute accept a fee for taking part in any consultation. Physicians desiring information concerning the activity of specimens of radium salts can obtain it from the chemico-physical laboratory of the institute at the following rates: measuring the amount of radium contained in specimens of radium salts, or measuring the amount of radium contained in various applicators, $10; analysis of the rays emitted from various applicators: preparation of radium applicators, circular or square disks, $10; cylindrical and special designs, $25; examination of water minerals and the like for radioactivity, $10. The institute is a handsome building situated in the west of London near Portland Place, well designed and thoroughly equipped. On the ground floor are rooms for the reception of paying and free patients and for diagnosis. The first floor is fitted up for the treatment of patients; the second floor is devoted to scientific research, and the third floor for a workshop and tools which make the institute independent of outside help in the matter of apparatus. On the ground floor there are five consulting rooms—two for paying and two for free patients and one for gynecologic examination. The medical superintendent is Mr. A. E. Hayward Pinch, F. R. C. S., who has already achieved a considerable reputation in the administration of the polyclinic of which he was for several years medical superintendent. The executive committee is composed of Sir Frederick Treves, Sir Lauder Brunton, Sir William Ramsay (the eminent scientist), Sir Malcolm Morris. The honorary consulting staff consists of a number of specialists: Mr. W. H. Clayton-Greens, Dr. Herbert French, Mr. W. H. H. Jessop, Dr. J. H. Sequeira, Dr. W. H. H. Tate, Mr. Herbert Tilley and Mr. F. Holding.

PARIS LETTER

(*From Our Regular Correspondent*)

PARIS, July 28, 1911.

Charles Nélaton

Dr. Charles Nélaton, surgeon of the hospitals and *agrégé* professor at the Faculté de médecine de Paris, has just died, aged 60, at his estate in Seine-ét-Oise, of an embolism. Charles Nélaton followed in the footsteps of his father, the celebrated surgeon of Napoleon III. The younger Nélaton had a sort of predilection for diseases of the bones and joints. He was especially fond of surmounting the difficulties of autoplastic surgery and his procedures in rhinoplasty especially have been much noticed. He published works on tuberculosis in surgical affections on benign tumors of the bones and, in collaboration with Ombredanne, two monographs devoted respectively to autoplasty in general and to rhinoplasty.

The Appearance of Cholera in France

The minister of foreign affairs has ordered the French consuls to report without delay all cases of cholera which may appear in their respective localities, so that measures may be taken with regard to travelers and merchants coming from these places. Unfortunately there is reason to doubt that these measures will be efficacious. A correspondent of the *Semaine Médicale* has observed how these precautionary measures are applied to travelers coming from and returning to Italy through Modane. Only travelers coming direct from an infected locality are detained. Therefore a traveler coming from Naples, for example, might take a ticket for Rome, and if he stops a few hours or minutes in the station without going into the city even, he might take another train direct from Rome to Paris with a new ticket and would not be stopped on the way. It is therefore not surprising that this surveillance has not been efficacious in some one of the four frontier stations and that some travelers coming from infected localities or from regions not officially declared infected have been allowed to pass without detention. Thus several cases of cholera have appeared in different quarters of Marseilles. The situation appears more serious in the department of l'Hérault of which Montpellier is the capital, where there have been a series of cases of cholera and of deaths from cholera in various localities.

Permanent Marking of Professional Criminals

Dr. Séverin Icard of Marseilles proposes a means of marking indelibly professional criminals by injecting under the skin a certain quantity of cold paraffin so as to make a small nodule. This nodule, not appreciably altering the appearance of the skin, would remain unnoticed by the uninitiated, and in case it should be discovered by accident by a third party, it might pass for a small cyst or some kind of tumor, whose judicial origin would not be suspected. The points of the skin chosen for the injection would vary according to the nature of the crime or the offenses and according to the dangerous character of the criminal. Dr. L. Sadoul writes in the *Caducée*: "This is evidently an excellent police measure which without barbarism or pain, permits a return to the old brand placed on convicts; but who will make the injection? If it is some jailer, there is reason to fear that the syringe may not always be aseptic. If it is a physician the condemned will have the guarantees of safety but the physician will lower himself to the level of an executioner. There is no discussion possible. Even if the prisoner consents the physican would still be lowering his professional dignity."

A Fake Philanthropist

For some time there have been scattered broadcast circulars headed "Oeuvre philanthropique" and couched in the following terms: "In the name of humanity, for the sake of God and men, I announce gratuitously to all how I was cured of that terrible disease tuberculosis after having been abandoned and condemned by all physicians. Let the sick take courage. Thousands of others seriously ill like me have been radically cured. It is my priestly duty to spread in the world this extraordinary discovery for the sake of God and humanity. For all information write to M. l'abbé Juillies, 26, rue Chanoinesse. Enclose a stamp for reply. Thousands of cures and testimonials! Preserve this advice with care; it will save the existence of those who are dear to you." Many have followed this advice and have written. It must be inferred that they were not satisfied with the result of their correspondence and their credulity, for the courts have been led to take a hand in the affair. The investigation shows that it was not an abbé but merely a tradesman who had taken this title the better to exploit public credulity and who was selling some kind of elixir at $1, $2 and $4 a bottle. The elixir promised to cure all kinds of diseases; tuberculosis, syphilis and baldness.

Syphilis in Prehistoric Times

The question whether syphilis existed in the old world before the fifteenth century or whether the companions of Christopher Columbus brought it from America, is not yet cleared up. In studying bones collected by the Baron de Baye in burial places on the Marne and preserved in the Museum of National Antiquities of Saint-Germainen-Laye near Paris, Dr. Paul Raymond, former *agrégé* professor at the Faculté de médecine de Montpellier, found a humerus and a cubitus belonging to different subjects which presented evident lesions of syphilis. Dr. Raymond concludes that syphilis, like tuberculosis, is as old as humanity and that America had no share in its propagation in Europe.

Personal

Dr. Antonin Imbert, major in the colonial sanitary corps, has died of the sequelæ of an anatomic puncture produced during a demonstration given in the amphitheater of the Ecole du service de santé des troupes coloniales.

The death of Dr. Charpy, professor in anatomy at the Faculté de médecine de Toulouse, is reported.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, *July 29, 1911.*

Personal

Professor Killian of Freiburg has accepted a call as the successor of Professor B. Fraenkel to the chair of laryngology at Berlin. In this way the question of which I have written has been happily solved. Our laryngologic clinic maintains its independence and receives for its head an investigator who is acknowledged as the foremost specialist in Germany. Moreover, we have at present no authority on laryngology in Berlin, so that the suffering public receives an essential advantage *from this appointment.*

Professor Fritsch of Bonn is to be succeeded by Professor *Menge of Heidelberg.*

Professor Wenckebach has accepted the call to Strasburg as director of the medical clinic.

Professor Bethe of Strasburg has at last accepted the call as professor of physiology at Kiel; his decision was delayed for many months on account of his illness as the result of an *operation for hernia.*

Professor Enderlen of Würzburg has been selected as the *successor of Professor Payr of Königsburg.*

Professor Kehrer of Bern, a son of the former gynecologist at Heidelberg, has assumed the direction of the gynecologic clinic at Dresden in place of Professor Leopold.

Jubilees

July 22, the semicentennial of the doctorate of Professor Waldeyer was celebrated at Berlin. The large participation of both natives and foreigners afforded another proof of the great esteem in which the 74-year-old scientist is held by his colleagues and the love and honor which is accorded to him by a large circle of the lay public. From many scientific bodies addresses and other marks of honor were presented. His pupils provided for a portrait bust and presented a memorial volume to which scientists of all lands have contributed. The Prussian government has awarded him the great gold medal for art and science.

July 24, Dr. Max Salomon also celebrated his golden doctor jubilee. He made himself noted, formerly, by several works in the field of medical history.

July 22, Professor Schmidt-Rimpper, the well-known ophthalmologist of Halle, celebrated his semicentennial as doctor.

July 25, the well-known pharmacologist, Professor Jaffe, of Königsburg, celebrated his 70th birthday. At the beginning of his career Jaffe was connected with the medical clinic at Königsberg as assistant of von Leyden. He published with Leyden an article on putrid sputum in which the discovery of the etiologic importance of spirilla and leptotriches for the lung process was announced. Of his pharmacologic works the chief are concerned with intermediary metabolism.

New Regulations for Hospital Construction

New provisions for the construction of hospitals, lying-in homes and infant homes were promulgated July 8, by the Prussian government, of which we will notice some of general interest. For hospitals it is required that the ground area of the building shall be at least 100 square meters (about 120 square yards) for each bed. The front wall of each hospital that is intended for the permanent accommodation of patients must be at least 20 meters (66 feet) distant from other buildings and the other walls 10. Before the windows of the patients' rooms such a free space must be provided that the enclosing walls and roofs of opposite buildings shall not extend beyond an air line drawn from the point of junction of the front wall of the building with the floor at an angle of *30 degrees with the extended floor line.* Each story which is intended for more than thirty beds must have two staircases which reach the open air. Vestibules and passages must be at least 1.8 meters (6 feet) wide, well lighted and capable of being heated and ventilated. Rooms whose floors are not at least 30 cm. (12 inches) above the adjoining earth surface must not be used for patients. Sick-rooms which are lighted from only one side must not have their windows to the north. Stairs in institutions with more than twenty beds must be fireproof and in all stories, including the roof story, must be surrounded by strong walls. They shall be without windings and be furnished with landings of equal width and shall be at least 52 inches wide. The treads must be at least 30 cm. (12 inches) wide and the risers at most 17 cm. (6.8 inches) high. The staircases must receive light and air directly from outside. The windows in rooms with several beds must have a surface equal to at least one-seventh of the floor space and in single bedrooms must have a surface of at least 2 sq. m. (2 sq. yds.). Each room for more than one patient confined to bed must have an air space of at least 30 cu. m. (cubic yard) with 7.5 sq. m. (sq. yd.) of floor space per bed and in single bedded rooms there must be an air space of at least 40 cu. m. (cubic yards) with 10 sq. m. (sq. yd.) of floor space; for children under 14, a space of 20 c. m. and a floor space of 5 sq.m. will suffice. For patients that are not confined to bed in rooms with more than one bed, and air *space of 24 cu. m. and for children under* 14 an air space of 14 cu. m. are sufficient if a sufficient day room *with at least 2 sq. m. of floor space* is provided. More than thirty beds may not be placed in one room. In every hospital there must be erected *for every ward or at least for every story a suitable day room* with its chief windows *not directed* to the north for the recreation of patients who can temporarily leave their beds; this room must have at least 2 sq. m. (sq. yd.) floor space for each patient and must in any case measure as much 20 sq. m. (sq. yd.). Besides, a recreation *yard* with a garden having as a rule a space of 10 sq. m. for each bed, must be provided. The water-closets must be sufficiently *extensive and at least* one water-closet must be provided for every fifteen beds for men and for every ten beds for women, properly furnished and separated from the ward. Special water-closets, separate from those for the patients, must be provided for the nurses.

In lying-in hospitals and infant homes and similar establishments or wards for this purpose in general hospitals there must be provided for each woman with her child, in rooms occupied by several puerperal patients, space of at least 35 cu. m. and in rooms for one woman with her child at least 45 cu. m. In rooms for infants an air space of at least 12 cu. m. must be provided for each infant's bed. For sick infants at least 20 cu. m. of air space must be allowed.

Competition in Infants

In September Berlin will have a baby show under the supervision of the matron of a welfare station. Of those entered, 150 children of mothers, selected by lot, are to be admitted to the actual competition. A classification of the children is provided for into those whose parents prefer a vegetable, a meat, or a mixed diet, and also into the children of drinkers or abstainers. The distribution of prizes will be undertaken by all the women who offer to compete, with the exclusion of those whose children are selected for the narrower competition.

Industrial Instruction for Cripples

The East Prussian agricultural trade union has lately arranged for courses for the instruction of cripples open to the members of their guild. In this way a number of invalids who were hitherto entirely unfit for work will be rendered at least partly self-supporting and social insurance and public charity will be relieved of part of their burden.

State Assistance of Midwives

In many country districts of Prussia, especially in the East, numerous births occur without professional assistance on account of the lack of midwives, which results in a considerable increase in illness and death, both of mothers and children. This lack is principally due to the insufficient opportunities for earning a living in these districts. In order to meet the most stringent need the Prussian government has appropriated 100,000 marks ($25,000) for the support of district midwives for the poorer classes.

VIENNA LETTER

(From Our Regular Correspondent)

Vienna, July 28, 1911.

Organization of Midwives in Austria.

The distribution and social position of midwives has long been unsatisfactory and has been the subject of much discussion in the public and in medical circles. Recently the "Union of Midwives" (Hebammen-Verband) of Austria sent a delegation to the minister of interior and to the minister of education, informing these authorities of the wishes and suggestions framed at the last meeting of the union. They desire a "numerusclausus" for their profession, on a scale of one midwife to 2,000 women of adult age, as well as fixed pay by the state in places where the quality of the population does not offer a likelihood of living for a midwife. This holds good chiefly for the country places and villages where at present there is no help for a parturient woman for miles around, because neither doctor nor midwife is within easy reach. Apart from that, the suggestions thrown out also provide for a tariff of fees for the women; as well as new regulations concerning the "curriculum." At present, one year of study at the gynecologic clinic is required. In future, two years should be spent in the midwives' school; the teaching to comprise the fundamental knowledge of anatomy and physiology of the pregnant and parturient female body, the necessary elements of bacteriology along with the surgical principles governing the process of childbirth. In order to enable the midwives to attain their aims, all women of the calling will be united in local and district branches to be called into existence soon, and it is intended to inquire also into the nature of diplomas and other qualifications possessed by the ladies at present.

The Heat in Austria

The most unusual weather conditions experienced in central Europe have had a very different effect in various places. Thus, in our country the sunshine during the first three weeks of July amounted to 260 hours, or fifty-five hours more than the average taken from the observations of 125 years. The rainfall was very small, only seven days instead of eighteen were classified as moist, with more than one hour's rain. At the same time, the temperature went up high, excessively high since the 19th, so that in Vienna the thermometer went up to 98 Farenheit in the shade! But in distinct opposition to the conditions prevailing during the heat wave in the United States, the humidity of the air was very low. Thus, perspiration was not interfered with, and we have had only a few cases of heatstroke up till now. The thirst of the population, however, is growing as the temperature is increasing. With us the iced drinks are not favored much, but from other reasons the daily use of ice has gone up from 100,000 bars—each weighing about 25 kilos—to 170,000 bars; at the same time the sale of milk, which generally diminishes in summer time to 600,000 liters, has gone up to 750,000 liters a day. The main reason for this is the extensive use of a favorite beverage, iced buttermilk, during the heat. As fruit is again very plentiful, this food has been used in enormous quantities, followed as usual by gastro-intestinal disturbances. Contrary to the expectations, the morbidity and mortality of infants and children has not been very high, at least up to the present. This is perhaps due to the dry heat which did not interfere with metabolism. It is a particular feature of our heat period this year that even the health resorts situated in the mountains did not escape its effects.

A Monopoly on Saccharin

The government has just presented to the parliament a bill which will make the manufacture of saccharin a monopoly of the state, like tobacco and salt. The monopoly shall comprise all artificial sweetening substances, except beet sugar or cane sugar. The sale of these articles will be licensed and the apothecaries will be the only persons who will obtain such a retail license. All articles of food containing saccharin will have to show it on the label and will thus be under special control. For persons who must not use sugar (diabetics) a special license may be granted and they will be able to obtain under it larger quantities of the substance at a reduced price, for their own use solely.

Marriages

Robert Lee Payne, Jr., M.D., Norfolk, Va., to Miss Mary Elizabeth Harmon of the University of Virginia, August 2.

Allen C. Beetham, M.D., Baltimore, to Miss Bertha Hewlett, at Merrick Long Island, N. Y., July 6.

Surgeon Lewis Morris, U. S. Navy, to Mrs. Ella Bingham Duffy of New York City, August 1.

Lisle W. Neiswender, M.D., Columbus, O., to Miss Mary Dennison, of Briggsdale, O., July 29.

George Baldwin Kroeger, M.D., to Miss Bertha Fay, both of St. Louis, July 27.

Lee E. Bransford, M.D., to Miss Blanche Royer, both of Baltimore, recently.

Deaths

Frank Pierce Foster, M.D., for more than thirty-one years editor of the *New York Medical Journal* and dean of the medical journalistic profession, died at Chadwick, N. J., August 13, from cancer of the throat, aged 69.

He was born in Concord, N. H., received his preliminary education in the public and high schools of that city, and graduated from the College of Physicians and Surgeons, New York City, in 1862. After a two years' internship in the New York hospital, he established himself in general practice in New York City where he has since resided, excepting for a short time when he served as surgeon on steamers running between New York and San Francisco, and in the fall of 1864 when for a few months he was contract surgeon in the United States Army. He engaged in general practice, but paid special attention at first to dermatology and later to obstetrics and gynecology. In 1870 he introduced the preparation and use of bovine vaccine virus into the United States under the auspices of the New York Dispensary and wrote a series of articles advocating the use of bovine as compared with humanized virus.

In January, 1880, he assumed the editorship of the *New York Medical Journal*, then a monthly published by the Appletons. Dr. Foster's energy and ability so improved the status of the journal that three years later it was made a weekly publication, and rapidly obtained its position as one of the leading medical weeklies of the United States. In the early eighties, Dr. Foster became editor and co-author of the illustrated "Encyclopedic Medical Dictionary" which bears his name and which occupied a large part of his attention for twelve years. He was also the editor of the "Reference Handbook of Practical Therapeutics" and a member of the editorial staff of the "Standard Dictionary."

Dr. Foster was a member of the American Medical Association and chairman of the Committee on Revision of Medical Nomenclature and prepared the reports presented by the committee at the sessions of 1909, 1910 and 1911. He was a member of the New York Academy of Medicine and the New York Gynecological Society, a member and once librarian of the Medical Journal Association, and secretary and president of the New York Dermatological Society.

Frank Wilfred Page, M.D. University of Vermont, Burlington, 1866; a member of the Boston Medical Library Association; from 1878 to 1880 assistant physician and superintendent of the McLane Hospital for the Insane, Somerville, Mass.; from 1897 to 1899 superintendent of the Vermont State Hospital, Waterbury; professor of nervous and mental diseases in the University of Vermont from 1898 to 1900; died at his home in Boston, August 2, aged 67.

Charles H. Brothers, M.D. University of Nashville, Tenn., 1872; a member of the Kentucky State Medical Association; formerly president of the Board of Health of Paducah; city health officer, and at various times president, secretary and treasurer of the Southwestern Kentucky Medical Association; died at his home in Paducah, August 3, from tuberculosis complicating nephritis, aged 61.

Charles Oliver Green, M.D. Bellevue Hospital Medical College, 1890; local surgeon at Hornell for the Erie Railway; captain and assistant surgeon, N. G., N. Y., assigned Third Infantry; a member of the staff of St. James (Mercy) Hospital; health officer of Hornell; was struck by an automobile while alighting from a street car, August 3, and died a few hours later from his injuries, aged 52.

Lawrence W. Hollis, M.D. University of Louisville (Ky.), 1883; formerly president of the Taylor County (Tex.) Medical Association; one of the board of examiners for the Thirty-Ninth Judicial District; proprietor of the Hollis Sanitarium. Abilene, Tex.; was struck by a falling timber during a wind storm in Abilene, July 31, and died soon after from his injuries, aged 49.

Thomas Crozier, M.D. Harvard Medical School, 1863; of Arlington, Mass.; a medical cadet during the Civil War; a member of the Massachusetts Medical Society; who was taken ill while at his summer home at Edgecomb, Boothbay Harbor, Me.; died in the Gregory Sanitarium at that place, July 25, from cerebral hemorrhage, aged 74.

John Baker Atchison, M.D. Long Island College Hospital, Brooklyn, 1867; a member of the American Medical Association; a Confederate veteran; a Montana pioneer and for the last twelve years a practitioner of Lewistown; died in St. Joseph's Hospital, Lewistown, August 2, from senile debility, aged 72.

John Beverly Warwick, M.D. Medical College of Ohio, Cincinnati, 1858; a veteran of the Civil War; for many years a member of the Hempstead Academy of Medicine, Portsmouth, Ohio; a member of the local pension examining board; died recently at his home in Lucasville, and was buried July 31, aged 77.

John Howard Crippen, M.D. Hahnemann Medical College, Philadelphia, 1872; a member of the American Medical Association, and Austin Flint-Cedar Valley Medical Society; attending physician at Presbyterian Hospital, Waterloo, Ia.; died at his home in that city, August 3, from nephritis, aged 60.

Arvid E. Osell, Medico-Chirurgical College of Kansas City, Mo., 1903; formerly assistant to the chair of clinical ophthalmology in the Medical Department of the University of Kansas; physician to the El Tigre Mining Company, near Douglas, Ariz.; died suddenly at his home, July 25, aged 43.

George John Schaller, M.D. Rush Medical College, 1881; a member of the American Medical Association; died at his home in Chicago, August 10, from the effects of a gunshot wound of the head, believed to have been self-inflicted with suicidal intent, while despondent, aged 51.

John Jacob Wuerth, M.D. College of Physicians and Surgeons, Chicago, 1898, of Chicago; a member of the American Medical Association; died at the home of his parents in Lawrence, Kan., August 3, from an accidental overdose of strychnin, aged 43.

William Richards, M.D. Long Island Hospital College, Brooklyn, 1862; University of Pennsylvania, Philadelphia, 1871; a member of the Massachusetts Medical Society; died at his home in Natick, July 27, from cerebral hemorrhage, aged 87.

James Marion Henry, M.D. College of Physicians and Surgeons, Baltimore, 1888; a member of the American Roentgen Ray Society; of Sioux City, Ia.; died at Hot Springs, S. Dak., July 26, from cancer due to *x*-ray burns, aged 51.

Lex Donald Wadley, M.D. College of Physicians and Surgeons, Little Rock, Ark., 1908; of Little Rock; a member of the American Medical Association; died in the Pulaski County Hospital, August 3, from uremia, aged 31.

Henry Albert Kirchner, M.D. Washington University, St. Louis, 1872; for twenty-five years physician to the German General Protestant Orphans' Home; died at his home in St. Louis, July 30, from nephritis, aged 61.

George Washington Fertich, M.D. Medical College of Indiana, Indianapolis, 1886; for twenty years local surgeon for the Panhandle System; died at his home in Dunkirk, Ind., August 3, from cerebral hemorrhage, aged 69.

Gregory Phelan, M.D. Cooper Medical College, San Francisco, 1880; for thirty years vice consul and deputy consul of the United States at Bordeaux, France, and Brussels, Belgium; died in the latter city, July 7.

Daniel Ayres Yarnell, M.D. Beaumont Hospital Medical College, St. Louis, 1889; died at his home in Eldon, Mo., July 29, from the effects of an accidental overdose of laudanum, aged 44.

Samuel P. Mitchell, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1875; died at his home in Mt. Etna, Ind., July 28, from the effects of an overdose of medicine, aged 64.

John W. Primm, M.D. Hahnemann Medical College, Chicago, 1878; for many years a practitioner of Woodstock, Ill.; died at his home in Pasadena, Cal., July 26, aged 60.

James Dunn, M.D. Tufts College Medical School, Boston, 1910; of Winthrop, Mass.; died at Boston City Hospital in December last from double pneumonia, aged 26.

William V. Anilosky, M.D. Medico-Chirurgical College of Philadelphia, 1907; died at his home in Lansford, Pa., July 29, from hemorrhage of the stomach, aged 27.

Milton A. Piper, M.D. Jefferson Medical College, 1871; a widely-known practitioner of Kensington, Philadelphia; died at his home in that place, July 26, aged 64.

William Cullen Bryant, M.D. New York Homeopathic Medical College, New York City, 1871; died at his home in Brooklyn, N. Y., July 22, from nephritis, aged 62.

Henley Boyd Newell, M.D. Rush Medical College, 1867; a member of the Racine County Medical Society; died at his home in Waterford, Wis., July 30, aged 66.

J. S. Gunn, M.D. University of Tennessee, Nashville, 1894; a member of the American Medical Association; died at his home in Adairville, Ky., August 1, aged 48.

George W. L. Hynds (license Tenn., 1889), a practitioner ever since the Civil War; died at his home in Hyndsver, Tenn., August 2, from heart disease, aged 74.

Edward L. Tracy, M.D. Chicago College of Medicine and Surgery, 1905; of Little Rock, Ark.; died at a sanitarium in Battle Creek, Mich., July 19, aged 37.

Jacob Bieger, M.D. Chicago Homeopathic Medical College, 1899; died at his home in Forest Park, Ill., August 6, from aortic aneurysm, aged 42.

James William Polhill, M.D. Medical College of Georgia, Augusta, 1908; died suddenly at his office in Hawkinsville, Ga., July 23, aged 37.

Louis P. Engleman, M.D. Louisville (Ky.) Medical College, 1897; was found dead in his office in La Fayette, Ind., August 7, aged 40.

Miscellany

Custody of Feeble-Minded.—Neither the prison nor the asylum is the right place for feeble-minded criminals, says G. A. Auden (*Jour. Crim. Law and Criminology*). There is no place for their custodial care in our present scheme of social polity, and we are driven to the strange conclusion that the best chance for the individual and for the society at large is, under existing circumstances, the commission of some serious crime, such as murder or arson, which will remove him for a lengthy period from further opportunities for antisocial action. By the removal from our penal establishments of the admittedly feeble-minded prisoners (on whom punishment and prison discipline are recognized as having no deterrent effect), the opportunities for greater specialization and classification of the same prisoners by the Borstal system, and by the recent regulations for the provision of humanizing influences, will be greatly increased. It is evident that an indeterminate sentence with statutory power to transfer to some form of institution which shall be substituted for the prison, affords the only satisfactory solution to the question.

Campaign Against Malaria.—A very effective campaign against malaria is reported by R. Ross in his book on "The Prevention of Malaria" as having taken place in Ismailia, a town founded by M. de Lesseps as headquarters of the Suez Canal Company. Since 1877, this town of 10,000 has been the scene of annual epidemics, the number of cases culminating in 1902, with more than 2,500, or 25 per cent. of the population! In 1902 a mosquito brigade was organized and the work directed chiefly toward the extermination of the mosquitoes, by draining a marsh near the town, filling up holes, visiting every house once a week and treating the cesspools with petroleum, in order to kill the mosquito larvæ, clearing all irrigation channels of reeds, so the water could flow swiftly, and by imposing penalties on the inhabitants if they did not cooperate in certain ways, the campaign was carried out to a magnificent success. While the number of cases annually during the years from 1885 to 1902 was seldom below 2,000, the years following the campaign showed the following reduction: 300 cases reported in 1903; 90 in 1904; 37 in 1905 and since then not one case has occurred! This campaign cost the town of Ismailia a trifle of $10,000 for the first year and $5,000 for the subsequent years. In the crusades against the diseases which swell the death-rate of the United States—diphtheria, scarlet fever and tuberculosis, to mention only the principal groups—the social-economic character of these problems has repeatedly been pointed out, but it has very often been difficult to convince taxpayers that preventive medicine is a paying proposition in the end. The report referred to above makes the problems a matter of simple bookkeeping; in 1902 the community of Ismailia transferred from the assets to the expense account the sum of $10,000 (or $4 per case of malaria) and the next year this community cleared a profit of 2,200 human lives redeemed from the disease. Does this look like a "business proposition" to our American taxpayer? Of course, it all depends on our standards of valuation!

The Human Air Sterilizer.—Every additional person present in the operating room is one more purifying machine for its air; is yet another means of lessening the possibility of germs from the air falling on the open wound in serious numbers as to the maintenance of surgical asepsis. The inhaled air, with its myriad impurities, is steadily filtered, as it were, and deprived of them during its passage from the nostrils to the pulmonary air-cells. Within the nose are the moist and sticky hairs; within a portion of the larynx, all of the trachea. and the bronchi and bronchioles are the cilia, active in our defense, first catching our little enemies and then (the cilia) continually lashing upward, carrying them away from our lungs the region of danger. Of course, additional persons breathing means just so much more carbon dioxid present in that room, also various more or less poisoned animal effluvia excreted by the breath. Poisons of this kind do not, however, affect the wound adversely regarding its asepsis. Microbes alone do this, and it is a well-known fact that, however dusty may be the air inhaled, when exhaled it is found to be practically sterile. In a well-kept operating room just prior to operation the floor is mopped with some antiseptic solution. Otherwise, particularly in dusty seasons and in dirty towns, each pair of shuffling or applauding feet may cause more trouble than that person's respiratory sterilizing plant can quell.—Dawbarn in *Medical Record.*

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

MAYR'S WONDERFUL STOMACH REMEDY

Another Fake Gall-Stone Remedy

The fake "gall-stone trick" and "tapeworm trick" have long been worked by itinerant medical swindlers. As every physician knows, the administration of large doses of some bland oil, such as olive oil, especially when followed by a saline cathartic, results in the passage of a number of greenish concretions from the bowels. The victim is made to believe that these concretions are gall-stones; and he feels that he is getting his money's worth in proportion to the number of these "stones" that are passed.

This method of defrauding the public is now being worked by "patent medicine" venders as well as by traveling fakers. In The Journal, Sept. 24, 1910, one of the most widely advertised of these fake gall-stone cures—"Fruitola"—was discussed. A number of inquiries have been received regarding the composition of another preparation of the same type, "Mayr's Wonderful Stomach Remedy," made by George H. Mayr, a Chicago druggist. One correspondent submitted a number of pseudogall-stones passed by one of his patients who had taken Mayr's nostrum. With the specimen the physician sent the following letter:

> "The accompanying specimen was brought to me by a patient whom I have been treating for membranous colitis. One of her symptoms is pain in the left side of the abdomen. There have been no attacks of biliary colic nor has the physical examination afforded any data on which to base such a diagnosis. On the advice of a friend the patient had taken 'Mayr's Wonderful Stomach Remedy,' which appears to be similar to 'Fruitola' recently exposed by you. I have found on a superficial examination that the masses which closely resemble gall-stones consist of a soap, part of which is insoluble. I would like to know whether the base of the insoluble portion of the soap consists largely of magnesia. If so, is it probable that this base is furnished by the saline cathartic given after the remedy or is a sufficient amount of earthy base excreted by the intestine to cause the formation of so large an amount of these pseudocalculi?"

To be able to answer this question intelligently, the Association's chemists analyzed not only the nostrum, but also the "gall-stones." The laboratory report follows:

LABORATORY REPORT

"Mayr's Wonderful Stomach Remedy" consists of a bottle of oil and two powders contained in a red carton on which appears the following:

> "Mayr's Wonderful Stomach Remedy for Stomach Troubles, Indigestion, Gases in the Stomach and Intestines, Dizziness and Fainting Spells, Colic Attacks, Torpid Liver, Constipation, Gastritis, Yellow Jaundice, Appendicitis, Gallstones, etc.

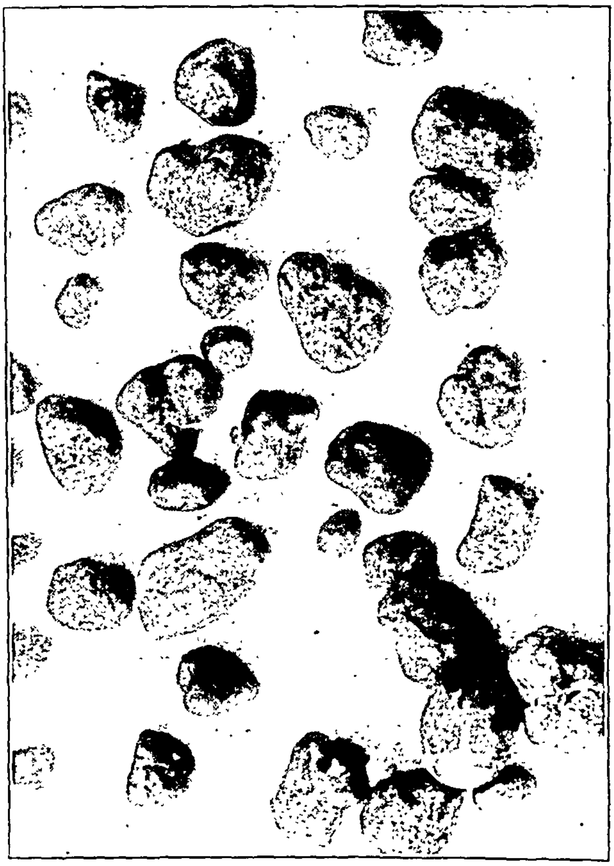

Fig. 1.—Photographic reproduction (actual size) of some of the supposed gall-stones passed by a victim who had taken Mayr's Wonderful Stomach Remedy. Anybody can perform the same trick by drinking a pint of olive oil and following it up with a seidlitz powder.

> "The above ailments are mainly caused by the clogging of the intestinal tract with poisonous accretions—which are caused by a catarrhal condition of the gall-bladder and duct, liver, stomach and intestinal tract—backing up poisonous fluids into the stomach, and otherwise deranging the digestive system.
>
> "This remedy painlessly removes these accretions without surgical operation, takes out inflammation from the entire intestinal tract and renders the same antiseptic."

A pamphlet comes with the bottle consisting chiefly of that sheet anchor of the patent medicine faker—testimonials. Of course, fraudulent claims are made.

> "Price $1.00 per bottle; worth $100.00."
>
> "A positive remedy for appendicitis."
>
> "It is composed of nothing but strictly pure food vegetable ingredients."
>
> "Unsurpassed for liver complaint."

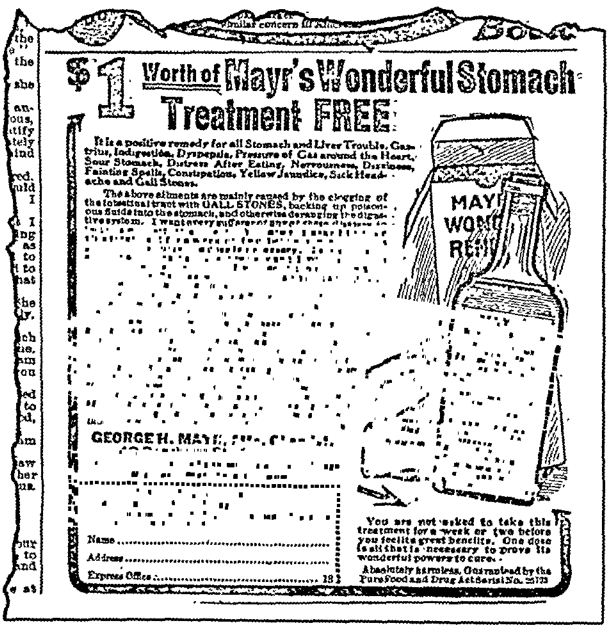
> "Those who believe that they have gallstones we implore you—*Don't submit to a dangerous surgical operation.* . . . The full course of Mayr's Wonderful Stomach Remedy not only painlessly removes this accretion, but allays the inflamed or catarrhal condition that causes them . . ."

The instructions for taking this nostrum directed the patient to take one powder at 3 o'clock in the afternoon; at bedtime the entire contents of the bottle (about a half-pint) was to be taken at one dose. The next morning the second powder was to be taken. The patient was told:

> "When the bowels operate use a vessel and note the poisonous secretions removed by this remedy, in some cases dark green or yellow lumps varying in size from a fine bead to an olive—in severe cases even larger. In other cases quantities of thick tenacious slime or mucous [*sic*]. These accumulations are weakening and poisonous."

The bottle contained about six ounces of a bland yellow oil, which from the results of analysis[1] appeared to be olive oil. The powders, each of which weighed about one ounce, appeared to be ordinary Rochelle salts one disguised by the addition of about 6 per cent. compound licorice powder and the other by the addition of about 4 per cent. powdered licorice root.

From the composition of the nostrum, as determined by analysis, it was expected that the concretions, which the physician had submitted for examination would be found to consist of a sodium soap formed in the intestinal canal by the action of the alkaline fluids on the fatty oil. As no magnesium was found in the preparation, the correspondent's suggestion that the "gall-stones" might be a magnesium soap did not appear plausible. Nevertheless it was thought worth while to demonstrate in a general way the composition of these masses.



$1 Worth of Mayr's Wonderful Stomach Treatment FREE

It is a positive remedy for all Stomach and Liver Trouble, Gastritis, Indigestion, Dyspepsia, Pressure of Gas around the Heart, Sour Stomach, Distress After Eating, Nervousness, Dizziness, Fainting Spells, Constipation, Yellow Jaundice, Sick Headache and Gall Stones.

The above ailments are mainly caused by the clogging of the intestinal tract with GALL STONES, backing up poisonous fluids into the stomach, and otherwise deranging the digestive system. I want every sufferer of

You are not asked to take this treatment for a week or two before you feel its great benefits. One dose is all that is necessary to prove its wonderful powers to cure.

Absolutely harmless. Guaranteed by the Pure Food and Drug Act Serial No. 2133

Fig. 2.—A reduced photographic reproduction of a typical advertisement of this fake gall-stone cure. From *Happy Hours*.

The so-called gall-stones, weighing in the aggregate about 21 grams (315 grains) were grayish-green and of the size shown in the illustration (Fig. 1). When received they had the consistency of soft wax, but on standing in the laboratory for several days the material separated into a dark oily portion and an amorphous gray part. Analysis[1] demonstrated the presence of both free and combined fatty acids as well as of considerable sodium and some potassium. Lack of material made it impossible to determine whether the combined fatty acids existed in combination with sodium or potassium or in the original condition as oil; for the same reason, it was impossible to determine in what form the sodium and potassium were present. As the amount of sodium found was in itself more than sufficient to account for all the combined fatty acids, it is probable that the masses consisted essentially of free fatty acids and soap (sodium salt of fatty acids).

In short, the so-called gall-stones are principally a mixture of fatty acids and soaps produced by the action of the alkaline intestinal fluids on the large amount of oil taken.

Correspondence

Purgation in Delirium Tremens

To the Editor:—After reading the article in the Therapeutics Department on "Delirium Tremens" in The Journal, August 5, I was struck by the omission of any reference to purgation. In the treatment of this condition, the incitement of an early and active purgation has seemed to me in the great majority of the cases the most important factor at our command. The thickly coated tongue, foul breath and unhealthy condition of the skin of many of these patients indicate that to the toxicity of the alcohol there is added the autotoxicity of faulty elimination. There is commonly a history of constipation and at times of inactive kidneys. An initial dose of from 3 to 5 grains of calomel followed in six hours by a saline has seemed to me so satisfactory that it has become my routine practice and is rarely contra-indicated. In severer cases I give from 3 to 5 compound cathartic pills and a cleansing enema on admission to the hospital and follow this with a saline. There are cases in which I employ immediate full doses of Epsom salts or even small doses of croton oil after 1/6 gr. of morphin hypodermically to obviate vomiting. Such measures, I believe, render the frequently required hypnotics less dangerous and more effectual. Such thorough elimination seems to cut short the course and severity of any delirium present and often to prevent the occurrence of a delirium which appears imminent. Further, the use of these hydragogues relieves congestions of cerebrum and other organs and may thereby avoid the incidence of an always dangerous edema of meninges or lungs. I believe the above an important addition to the very helpful measures outlined in The Journal for the treatment of delirium tremens.

C. C. Wholey, Pittsburg.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

SERIAL DILUTION OF KOCH'S TUBERCULIN FOR THERAPEUTIC USE

To the Editor:—Please publish the method of serial dilution of Koch's new tuberculin for therapeutic administration; also, some references in the literature. J. J. Zaun, St. Paul, Minn.

Answer.—The dilution should be made with normal salt solution plus 20 per cent. of glycerin.

The original solution constitutes solution No. 0. If 0.1 c.c. of this solution be mixed with 0.9 c.c. of the diluent we get solution No. I; 0.1 c.c. of solution No. I mixed with 0.9 c.c. of diluent gives solution No. II; 0.1 c.c. of solution No. II mixed with 0.9 c.c. of the diluent gives solution No. III. The dose to be administered at first should be so small as not to produce a reaction. It should be gradually increased by using fractions of a cubic centimeter of the solution until 1 c.c. is given at a dose. The transition is then made to the next stronger solution, 0.1 c.c. of which is equivalent to 1 c.c. of the weaker. The increase of dose by advancing by 0.1 c.c. of this stronger solution is usually too abrupt. This is avoided by giving 0.5 c.c. of the weaker solution with 0.1 of the stronger, the dose thus given amounting to 0.15 c.c. of the stronger solution. The doses are thus gradually increased until 1 c.c. of solution No. II is used when the transition is made to No. I and finally to No. 0 in the manner described. It is not advisable to make up more than 1 c.c. of tuberculin solution at one time.

The literature of tuberculin therapy is so extensive that it is not practicable to publish references to it.

SODIUM CHLORID IN EPILEPSY, GASTRIC ULCER, ETC.

To the Editor:—Please give me references to articles on the following topics:

1. The effect of the ingestion of sodium chlorid in epileptics.
2. The effect of the ingestion of sodium chlorid in hyperchlorhydria and ulcer of the stomach.
3. The effect of the ingestion of sodium chlorid in dropsy of renal or cardiac origin
4. The effect of the ingestion of sodium chlorid as causing chronic interstitial nephritis, and incidentally arteriosclerosis, by increasing blood-pressure and inhibiting osmosis through the renal capillaries.

T. I. O'Drain, Philadelphia.

EPIDEMIC PNEUMONIA—A QUERY FROM INDIA

To the Editor:—As a regular reader and admirer of THE JOURNAL, I am particularly struck with the wealth of references which you and your contributors always muster. I shall therefore be most grateful if you will answer, or cause to be answered, the query below; up to [illegible] my search for literature bearing on the subject has been most disappointing. Please give me references to literature on epidemic pneumonia, especially as regards its etiology.

C. B., Meerut, U. P., N. India.

ANSWER.—Pneumonia occurs in epidemic form under various circumstances. The following factors may be noted as contributing to its epidemic character: 1. Unusual virulence of the pneumococcus. 2. Occurrence in connection with another disease of epidemic character, such as influenza, plague, etc. 3. Marked opportunities for conveyance, as in institutions like jails, asylums, etc. 4. Circumstances that lower resistance of a number of people. It is impossible from this distance to say what are the special circumstances which make possible the epidemic of which our correspondent writes, but it is to be hoped that a thorough investigation will be made resulting in a valuable contribution to medical science.

The following references to literature on epidemic pneumonia may be consulted:

STRONGYLOIDES STERCORALIS

To the Editor:—Please outline for me a satisfactory treatment for an enteritis resulting from an infection from *Strongyloides stercoralis*. Thymol has been tried in various methods for a considerable length of time without appreciable results.

F. H. STIBBENS, U. S. Navy, San Francisco.

ANSWER.—The results obtained in the treatment of infection by *Strongyloides stercoralis* have been unsatisfactory for the reason that the parasites burrow into the mucous membrane of the intestines and thus render it difficult for a drug to reach them. Thymol has been much used, but, while it seems to be as efficient as any drug, it is often of little or no value. In case of failure with thymol, aspidium (male fern) might be used. The administration of glycerin has been recommended by Preti, the patient receiving 50 gm. (1⅔ oz.) of pure glycerin by the mouth and 30 gm. (1 oz.) by the rectum, two hours later. After two days, the procedure is repeated.

STRANGULATED HERNIA WITHOUT VOMITING

To the Editor:—In THE JOURNAL, June 24, 1911, page 1882, Dr. Judd reports a case of strangulated hernia without vomiting. I note, however, that his patient was a Chinaman. During my service in China I operated on a man in Peking for a left inguinal strangulated hernia; the tumor was about the size of a quart jar and had been strangulated between twenty-four and thirty hours. This man had not vomited at any time nor had his bowels moved since the strangulation. Operation and recovery were uncomplicated. I saw about two such cases among the Chinese, but have never seen one case in an American in which vomiting did not occur.

This recalls a case I had in Peking. A man, aged 30, came to the hospital for relief. The one thing he needed was to have his stomach unloaded. I gave him 20 grains of zinc sulphate. He lighted his pipe and began to smoke. There were no results. I then gave him, hypodermically, 1/10 grain of apomorphin. He continued to smoke. I tried several vaunted emetics on him. He retained them with complacency. Finally, I washed out his stomach. It needed it badly.

JOHN INGLIS, Denver.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Aug. 5, 1911.

Baily, Howard H., captain, detailed for service assigned Major C. R. Reynolds, Medical Corps, as inspector and inspector Ambulance Company, D. C. Militia, Frederick, Md., Aug. 18-27, 1911.

Boehs, Charles J., M.R.C., ordered to Fort Porter, N. Y., for temporary duty.

Fisher, Henry C., lieut.-col., left Columbus Barracks, Ohio, en route with recruits to Fort McDowell, Cal.

The following-named officers will proceed at the proper time to the camp of organized militia for duty as inspector instructors of militia and on completion of this duty will return to proper stations.

Wilcox, Charles, lieut.-col., is ordered to Springfield, Ill., August 12 to September 2.

Fuller, Leigh A., major, is ordered to Nevada, Missouri, August 20-27, to Ottumwa, Iowa, August 28 to September 6.

Skinner, George A., major, is ordered to camp near Morristown, Colo., September 12-16.

Van Pool, Gideon McD., major, is ordered to Dixon, Ill., August 12-26.

Van Dusen, James W., major, is ordered to Fort Riley, Kansas, August 7-16.

Grissinger, Jay W., captain, is ordered to Des Moines, Iowa, July 20-29, to Vinton, Iowa, August 7-16, and to Shenandoah, Iowa, August 21-30.

Blanchard, Robert M., captain, is ordered to Sparta, Wis., September 1-30.

Jones, Percy L., captain, is ordered to Wheatland, Wyo., August 13-21.

Owen, Leartus J., captain, is ordered to Elgin, Ill., July 29 to August 26.

Williamson, Llewellyn P., first lieut., is ordered to Jimmie Gulch, Colorado, September 19-23.

Clarke, Howard, first lieut., is ordered to camp near Omaha, Neb., September 27 to October 6.

Buck, Carroll D., major, is granted leave of absence for one month to take effect about August 15.

Norman, Seaton, first lieut., is granted leave of absence for one month and twenty days, to take effect on his relief from duty Fort Leavenworth, Kan.

Halliday, Charles H., M.R.C., is granted leave of absence for two months.

Williamson, Llewellyn P., first lieut., is ordered to Camp Perry, Ohio, to report to executive officer of National Matches for special duty August 12-30, and on completion to return to proper station.

Poust, Luther R., M.R.C., is assigned to permanent duty at Fort Du Pont, Del.

Chilton, Frank N., lieut., left San Antonio, Texas, with Third Field Artillery, en route to Fort Myer, Va.

Darnall, Carl R., major, left Washington, D. C., on one month and ten days' leave.

Dickinson, C. F., M.R.C., left Fort Duchesne, Utah, with troops on practice march.

Walkup, Joseph O., lieut., left San Antonio, Texas, en route to Army General Hospital, Fort Bayard, N. Mex.

Lake, George B., lieut., reported for duty at Fort Sheridan, Ill.

Etter, Harry B., lieut., reported at Camp Fort Bliss, Texas, from duty in field Novia, N. Mex.

Van Kirk, Harry H., M.R.C., is ordered to report to the president of the Army Medical School for duty as a student.

Moncriel, William H., captain, ordered to proceed from Fort Leavenworth to Fort Sheridan, Ill., for duty with troops from latter post at encampment at Port Huron, Mich.

Flynn, Thomas J., lieut., ordered to proceed from Fort Snelling to Fort Brady, Mich., for duty with troops from latter post at Camp Perry, Ohio.

Ingalls, Raymond E., dental surgeon, now at Fort Apache, Arizona, will proceed to Whipple Barracks, Arizona, for temporary duty.

Miller, Edgar W., captain, is granted fourteen days' leave of absence.

Leary, Thomas J., first lieut., is granted leave of absence for three months on his arrival in the United States.

Smith, Allen M., lieut.-col., is relieved from duty at Fort Sam Houston, Texas, when no longer needed at Base Hospital, and will proceed to Fort Snelling, Minn., for duty.

Ragan, Charles A., major, promoted to, with rank from July 14, 1911.

Medical Corps, U. S. Navy

Changes for the week ended Aug. 5, 1911.

Nash, F. S., medical inspector, orders of July 27 revoked.

Bishop, L. W., surgeon, commissioned surgeon from Aug. 24, 1910.

Strine, H. F., surgeon, commissioned surgeon from June 2, 1911.

Elliott, M. S., surgeon, detached from the Naval Medical School, Washington, D. C., and ordered to duty in connection with the *Utah* and to duty on board that vessel when placed in commission.

Huff, E. P., P. A. surgeon, commissioned P. A. surgeon from July 12, 1910.

Schmidt, L. M., P. A. surgeon, commissioned P. A. surgeon from December 28, 1910.

McDowell, R. W., P. A. surgeon, commissioned P. A. surgeon from May 18, 1911.

Whiteside, L. C., and Thomas, G. C., P. A. surgeons, commissioned P. A. surgeons from June 15, 1911.

Brown, E. W., asst.-surg., ordered to duty at Quincy, Mass., in connection with submarines.

Traynor, J. P., surgeon, commissioned surgeon from July 11, 1911.

Gill, J. E., P. A. surgeon, detached from the navy recruiting station, Cleveland, Ohio, and ordered to the *Wabash*.

Parham, J. C., asst.-surg., commissioned asst.-surg. from July 7, 1911.

Shepard, G. W., asst.-surg., ordered to the navy recruiting station, Cleveland, Ohio.

Nohle, H. D., asst.-surg., detached from the *Villalobos* and ordered home to wait orders.

Ledbetter, R. E., surgeon, detached from the bureau of medicine and surgery and ordered to the naval hospital, Washington, D. C.

Dunn, H. A., surgeon, detached from the naval hospital, Washington, D. C., and ordered to duty in connection with fitting out the *Florida* and to duty on bo[illegible]

Rhodes, G. C., P. A. surgeon [illegible] al hospital, Port Royal, S. C., and ordered [illegible]

Bunker, C. W. O., P. A. surgeon, detached from the naval hospital, Mare Island, Cal., and ordered to the navy recruiting station, Los Angeles, Cal.

Hoyt, R. E., P. A. surgeon, detached from the naval hospital, Mare Island, Cal., and ordered to the navy yard, Mare Island, Cal.

Jones, E. L., P. A. surgeon, detached from the navy recruiting station, Dallas, Texas, and ordered to duty on the Asiatic station.

Brown, H. L., P. A. s[illegible] avy recruiting station, Los Angeles, Cal [illegible] month [illegible]

Bacon, S., asst.-surg., [illegible] and ordered to command of the nava[illegible]

Riddick, W. J., asst.-s[illegible] *Carolina* and ordered to the *Wheeling*.

Boland, M., asst.-surg., detached from the naval hospital, Philadelphia, Pa., and ordered to the navy recruiting station, Dallas, Texas.

Sanborn, C. F., acting asst.-surg., ordered to the marine recruiting station, Denver, Colo.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POSTGRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

THE EVILS OF THE CONTRACT-SYSTEM

Report of the Committee Appointed by the Erie County Medical Society to Investigate Unethical Contract-Practice

(Presented at Regular Meeting, held at Buffalo, N. Y., June 19, 1911)

The committee appointed to investigate contract-work wishes to report the result of its investigation up to date, and the remedy which it deemed proper that this society should adopt in order to eradicate this evil. We found it to be so widespread as to necessitate careful and close analysis, making it impossible for the committee to hand in a complete report at this meeting. From the data which came under our observation, we estimate conservatively that at least 150,000 people in this city alone are securing professional services under unethical contracts. I say that our work is incomplete, made so by the magnitude of the evil and the length of time at our disposal in which to cover it. But in justice to this society, we cannot offer any report without giving a specimen of the despicable, penny-contracts held by many of the physicians of Buffalo. The following section relative to the duties of the physician, taken from the by-laws of an organization known as the Fraternal Order of Eagles, is self-explanatory.

> SECTION 1. It shall be the duty of the Aerie physician to attend, prescribe for, and perform such surgical work as may be necessary, on all members of the aerie in good standing and their respective families, also all visiting members and their families without extra charge, except in cases of confinement and primary venereal or chronic diseases, or disabilities existing at the time the member made application for membership.

There are two other organizations which offer contracts similar to the above that came under our notice. These organizations are known as the Loyal Order of Moose and the Fraternal Order of Orioles. All these organizations exist throughout the country. We found that there are a number of other fraternal insurance organizations which offer contracts of a like nature operating in this city. Among these are the American Order of Foresters, the Order of Red Men, the Maccabees and various other societies with peculiar appellations. We found that certain liability insurance companies have physicians under contract to care for their policy-holders in case of injury. These physicians are paid a miserable pittance, primarily, to cooperate with the insurance companies against the poor unfortunate who unknowingly gets into the web which the greedy, cunning, and malicious spider has so craftily and slyly woven around him. This insectivorous professional cooperates with the liability insurance company at the expense of his innocent and trusting patient to prevent liability. This, in my opinion, is an offense which should be punishable by law.

We found that a number of the large corporations of this city have fostered a movement of their employees to form associations which are supported by regular weekly assessments, primarily for their own benefit, and secondarily for the benefit of their employees. The employee is the actual supporter of this association while the employer receives the greater part of the benefit. By this arrangement the employer undergoes no inconvenience. The association supports itself: It hires a physician not only to care for its members when injured while at work, but also arranges to have the physician care for any of them for any physical disturbance which may arise during the time of the contract. In some cases they have hired the physician at a regular monthly salary to care not only for themselves, but for their families as well. They have had no difficulty in securing the services of a physician to engage in this admirable, lofty, and sublime work. Of course, the corporation sees to it that one friendly to its interests secures the position. It is absolutely necessary for the corporation to secure the services of an "honorable man" to perform the duties of this high office. He must work for the interest of the corporation and against the interests of the employees. Whenever there is an injury to any of the employees, the actual supporters of the physician, he must have the welfare of the corporation at heart, and do his best to prevent litigation. What a fine clock-wheel arrangement this is!—the corporation works its employees, the employees work the doctor, the doctor works the corporation, and they all work one another.

We found that practically the entire Italian male population of Buffalo is entitled to medical services under cheap contract, and that the doctors holding these contracts, in some cases, are caring for the families at cut rates, and a few are giving medicine free of charge. This system has grown from bad to worse. As the field of competition increases, the younger graduates are taking up the work more cheaply than their predecessors. What is the result of this mad competition? The physician has thrown off the dignity of his profession and has stooped to the acceptance of a mere pittance as compensation for his professional services. Of course, the number of patients he must call on is great, and he cannot, therefore, render to each individual the medical attention required, for he must "be up and doing," as he must utilize every minute to the best of his personal advantage. Under such a system there is no incentive to do good work. The people do not realize their danger, and something must be done to educate them to the fact that, far from gaining any salutary advantage, they are committing the greatest folly. The doctors of Italian origin who are holding these contracts realize their mistake, and have given the committee to understand that they would be only too willing to give up their contracts were it not that they fear that some of the American doctors would only too readily take up the work which they should abandon. Such is their plight, and, if these men sacrifice their penurious positions, this society must do all in its power to prevent the niggard and avaricious medicaster from taking their place. Among the Polish population the same system is in vogue, but we are not prepared to state the extent of it in this report.

Another phase of this work was brought to our attention. We learned that a large number of the department stores and other business places have associations which contract with the physician in the same manner. Indeed, this system has become so wide-spread that even a number of the labor organizations have adopted it as "a good thing."

A certain institution which advertises itself as a hospital, engages in wholesale contracts for an infinitesimal amount, to care for its policy-holders, who may be individuals or families, for any illness of any nature whatsoever. This institution has a dispensary where colored solutions under alphabetical labels are dispensed by an undergraduate. We have learned of still another method of securing "the almighty dollar." We learned that a certain Dr. Richardson, whoever he may be, with some twenty others, have prepared a very grandiose and elaborate work which they are handing out at the rate of $10 per copy, and charging $2 extra which entitles the holders of the certificate to free consultation for a period of two years. There is a cooperative plan of procedure between the local representative agent of this erudite organization and a certain leading drug-store which enables them to complete the chain of their depredations most thoroughly. While this very idea smacks of the rankest quackery, yet it is no worse than some of the other cheap contracts held by supposedly regular men. The only difference between them is that one is direct while the other is an indirect mode of procedure.

Another form of contract considered by your committee is one which will tax our efforts to obtain evidence. It was said that some physicians are in the habit of contracting with their patients prior to their illnesses for sums varying from ten to one hundred dollars annually. If such practice is in vogue, it must be most heartily condemned. This gambling game deserves the severest criticism. The physician who practices it is unscrupulous and mercenary. It is an imposition upon society, and, like all other unethical contracts, must be stigmatized with the utmost opprobrium.

We found that each railroad entering Buffalo has its surgeon under annual contract to care for its employees, or any one except a trespasser who may happen to be injured. We do not know the salary paid to these surgeons, but we understand that it is comparatively small for the services required. The action of the committee in attacking the contract-system must not be misunderstood. We do not care whether the physician is overpaid or underpaid. We are attacking it because the principle underlying it all is unethical, unjust, and, in every case, injurious to the profession in general. The surgeon who holds a railroad contract holds it with the proviso that he cooperate with the railroad and work against the interests of the poor unfortunate who happens to come under his charge. This is, of course, a good thing for the railroad, a nice thing for the surgeon, since it nets him a yearly salary, but a very bad thing for the public. We found that, undoubtedly, this particular form of contract is the grandparent of the rest. In justice to our sense of fairness, we could not possibly take any action against the small offenders without attacking these polished violators of the ethical laws who are seemingly responsible for all the others.

We believe that the above covers concisely the whole of the contract-system. The causes of these existing evils were offered by the committee, and are as follows:

1. Lack of knowledge of the ethics of medicine.
2. Professional jealousy.
3. Indifference of the older practitioners.
4. The example set by some of the older practitioners.
5. Overcrowding of the profession.
6. The tolerance of this state of affairs by all medical societies.
7. The commercialism of the age. The professional struggle not only for the almighty dollar but also for the mite(y) cent.
8. The chief cause of all, however, we found to be the complete disorganization of the medical body. This is the phase of the question to which we must give our attention, namely, the disorganization of the medical body.

This evil has been growing insidiously in all its various forms for some time, and has been passed unnoticed by the powers which should have throttled it in its infancy. It may be that the older members of the profession have been swollen with false pride, deeming such considerations beneath their dignity, or it may be that they have had no idea of the extent or character of this pernicious evil. Be that as it may, our investigation has disclosed a state of affairs tolerated or disregarded by the medical fraternity which should never have been permitted to exist. When the true state of affairs was brought to the notice of your committee, some were in favor of adopting extreme measures, but the more conservative element prudently advised the adoption of persuasive measures. The first action of the committee was to send out return postcards to every member of this society. In the short interval of ten days, 225 cards were returned—all save three of which were in favor of this movement. The three cards against it bore no signatures. At the subsequent meeting of the committee, such returns as this showed us that the profession was alive, and, from the remarks on some of the cards, heartily willing to cooperate with the committee. The cards against this movement were without signatures, so that, whatever opposition there is to it, comes from those who have not the courage of their convictions. A second notice was sent to all those members who had not returned the card, reminding them that they had either overlooked or misplaced it, and up to the present date, we have 320 members of this society pledged to support this movement. We are aware of some few men who are opposed to it, but only one of them has had the courage to sign himself against it. The committee charitably refrains from mentioning his name.

In the short time that this committee has had to act, it is sorry to say that it cannot offer a more complete report. Your committee shall not spare its efforts until every man is located who has the audacity to stand for such a system as has been brought to your notice. While almost two-thirds of the members are pledged to this movement, there yet remain about two hundred who have not stated their position, and the committee shall continue its investigation until every member has taken a definite stand. We believe that after every one who has not answered has been interviewed, there will be very few in the opposition. As the committee has been very conservative in the measure it proposes to adopt, it hopes that it will be *heartily approved by this society. Many radical* suggestions were offered, but, after much deliberation, it resolved to adopt the following:

Resolved, That the proposed amendment, if adopted, shall *not apply to present contracts, but shall prohibit any* extension or renewal of the same—except by action of the society, at a regular meeting, upon request of the interested physician.

Add a section to Chapter II of the Constitution and By-Laws to be known as section 13, and to read as follows: No one shall *become a member of this society or continue as such who* engages in contract-work, unless it be governmental in character, but this shall not prohibit an agreement for a particular case nor apply to examinations for an adequate fee.

We further recommend: 1. That the President appoint *from time to time at his own discretion, special committees* to use their influence on any man who continues this unethical practice whether he be a member of this society or not.

2. That a special committee be appointed to confer with the membership committee to devise ways and means to get all desirable men in this society.

3. We recommend that the proper authorities of this society bring this matter to the attention of the State Society for the purpose of gaining its support.

4. That this society meet more frequently, that its members *become more united, and that self-interests be put aside for* the common good of all.

We feel that the above resolution, amendment, and recommendations are not too radical. The various faddists, quacks, *pseudoscientists, and charlatans are the sins of our neglect.* Are we going to commit more sins of omission? The evils dealt with in this report and practiced by the supposedly regular members of the profession should not be tolerated any longer. We must separate the unethical from the ethical practitioner. We must ostracize him as we have the advertising quack. Nay, we must do more. We must use antagonistic measures if persuasion fails to convince him of his error. The methods of antagonizing him have been discussed *by the committee, but it is not our purpose to speak of them* in this report. We address ourselves so strongly because we feel sure that after all the cards have been returned, there will be very few offenders left. To these men we offer fellowship not only in this society, but, through it, also to the society of the state and nation. The membership of this society consists of practically all the physicians of Erie county. Many of the men who do not belong to this society are those who have graduated in medicine within the last few years, *and most of these can be easily induced to become members.*

The above is the situation which is now confronting us. It is high time for us to separate the sheep from the goats. If medicine is a profession, if it stands for something more than mere commercialism, if it possesses every quality that is honorable and noble, then we should do nothing to degrade it. We should rather raise it until it has reached the climax of ethics, and its standard has become the highest obtainable. But this can never be accomplished by suffering the contaminating presence of men who engage in degrading work to remain within this or any other medical body. If there be any set of men who wish to continue this debasing practice, let them be separated from those who have enough principle and honor to deem such work beneath the dignity of the medical profession. We therefore recommend that this society use every possible effective measure to bring this about, and purge itself of all those who are unworthy to be regarded as its members. We have not been guided by animosity or actuated by malice in arriving at our conclusion. We have no feeling of resentment toward any man. We have consistently considered big and little offenders alike. We believe in the utmost charity to all, for even your committee has among its members men who are or have been violators. Yet, in justice to our profession, besmeared in the mire of commercialism, we have been compelled to suggest the proposed amendment. With the confidence of honesty, we submit it for your consideration, knowing that the urgency of the situation demands every honorable man's support.

COMMITTEE ON CONTRACT-PRACTICE,
EDWARD E. HALEY, Chairman.

The following questions were asked:

ANATOMY

1. Describe the endocardium. 2. Give origin, branches and parts supplied by the musculo-spiral nerve. 3. Name five muscles of the shoulder and arm. Give origin, insertion and action of any *one* of the five 4. Name the muscl
of the femur. 5. What are the
vein? 6. Mention an anastomos
veins. 7. Name, locate and describe the largest of the cranial ganglia. 8. What nerves supply the knee-joint? 9. In what respect do the pulmonary differ from other veins? 10. Describe the facial vein. Name its tributaries. 11. Describe the long saphenous vein. 12. What muscles (*a*) elevate, (*b*) depress the os hyoides and the larynx? 13. In fracture of the shaft of the radius near its center, what muscles are involved in displacement of the fragments? 14. Name and describe the different glands of the stomach. 15. In what way do the axillary and deep cervical glands communicate with each other.

HISTOLOGY

1. Give composition of human blood. 2. Mention different leukocytes and derivation of names. 3. What are thrombocytes? 4. Give structure of the mucous membrane of the stomach. 5. What cells line the larynx, trachea, bronchi and bronchioles?

PATHOLOGY

6. Give rôle of white blood-cells in infection. 7. What is hemolysis? 8. Define agglutination. How produced? 9. Define atelectasis; give causes and effects. 10. What will cause and what are the effects of exclusion of bile from the intestines?

BACTERIOLOGY

11. Give chemical composition of bacteria. 12. What are proteid bodies? Name varieties and describe them. 13. What substances must be supplied to bacterial cells for their food? 14. Mention other bacterial functions besides disease production. 15. What are the fermentations of milk? Which are innocuous and which harmful? State effects of pasteurizing and boiling.

PHYSIOLOGY

1. What chemical change is necessary for blood coagulation? 2. Is the alkalinity of the blood increased or diminished by exercise, lactation or digestion, and why? 3. State the normal amount of blood in a man weighing 160 pounds. How is it renewed after hemorrhage? 4. What is absorption, and by what process is it accomplished? 5. What conditions favor, and what conditions retard, absorption? 6. State the origin and function of lymph. Is it coagulable, and why? 7. What tissues and organs are developed respectively from the ectoderm, mesoderm and entoderm? 8. What are the Wolffian bodies, and what becomes of them? 9. Discuss the *corpus luteum. Does it indicate pregnancy? Explain.* 10. What principal centers are located in the medulla? 11. What are the functions of the brain membranes? 12. Compare the functions of the white and gray matter in the encephalon. 13. Name, *in order of importance*, the organs in which animal heat is developed. 14. What variations of temperature are found in different parts of the body? Why? 15. Can a man live on an exclusively meat diet? Why?

CHEMISTRY

1. (*a*) How does uric acid form in the system? (*b*) Of what are gout stones principally composed? (*c*) What is the solubility of uric acid? 2. (*a*) State the origin of tartaric acid and other tartrates. (*b*) Give chemical formula of cream of tartar. (*c*) Rochelle salt. 3. (*a*) What are fats chemically? (*b*) What becomes of the fats ingested and what is the province of adipose in the body? (*c*) Under what condition does fat occur in the urine? 4. (*a*) What is nitroglycerin? (*b*) How is it used in medicine and what is its effect on the vascular system? 5. (*a*) What is chloral hydrate? (*b*) How does chloral act as a poison? 6. (*a*) What is the difference between ferrous and ferric salts? (*b*) Give examples by formulas. 7. (*a*) What is potassium permanganate? (*b*) Give formulas and its action as a disinfectant. 8. (*a*) Which are the two iodides of mercury? (*b*) Give formulas. (*c*) What is the difference in action of the "ous" and "ic" compounds of Hg? 9. (*a*) Define the term hardness as applied to a potable water? (*b*) What does the presence of an abnormal quantity of chlorides in a drinking water indicate? 10. Name three pigments normally present in human urine. 11. (*a*) Name three univalent elements. (*b*) Name a monobasic, a dibasic, and a tribasic acid radical. 12. (*a*) Give source, symbol, valency and atomic weight of bromin. (*b*) What is acidum hydrobromicum dilutum (U. S. P.). 13. (*a*) What is oxalic acid? (*b*) For what salt is it liable to be mistaken? (*c*) Give treatment for poisoning by oxalic acid. 14. (*a*) What are the principal constituents of cow's milk? (*b*) Give chemical explanation of the souring and curdling of milk. 15. Name the alkaloids of belladonna, aconite, nux vomica and opium.

PRACTICE OF MEDICINE

1. Describe bubonic plague. 2. Differentiate tonic and clonic spasms. 3. Describe the different stages of syphilis. 4. Differentiate cystic and renal hematuria. 5. Give the causes and symptoms of cholelithiasis. 6. Give the causes and symptoms of edema glottidis. 7. Give four physical signs present in consolidation of lung tissue. 8. How would you determine high blood-pressure? What is its significance? 9. What, how much and how often should a four-months-old bottle-fed baby be fed? 10. Differentiate ataxia and aphasia, and give the location of the lesion in each. 11. Where is bronchial breathing heard normally? What does it indicate when heard elsewhere? 12. What is the significance of (1) epithelial; (2) granular; (3) fatty and (4) waxy casts in the urine? 13. Describe the prodromal symptoms, giving the duration of each in (1) scarlet fever; (2) measles, and (3) small-pox. 14. Give three causes for specific gravity of the urine (1) under 1010, and (2) over 1030, and the significance of each. 15. Describe vesicular, papular and pustular inflammation of the skin and name a disease of which each is characteristic.

SURGERY

1. Diagnosis and treatment of perforation of intestine in typhoid fever. 2. Give etiology, diagnosis and treatment of empyema of the frontal sinus. 3. Give symptoms and treatment of ischiorectal abscess. 4. Treatment of compound fracture of tibia and fibula. 5. Describe tertiary syphilis of the pharynx. 6. Diagnosis of embolism of the mesentery. 7. Mention the causes of incontinence of urine. 8. What are the symptoms of cerebral compression? 9. Describe in detail lumbar puncture. 10. Diagnosis and treatment of papilloma of the bladder. 11. Give indications for drainage. 12. Mention the causes and symptoms of stricture of the rectum. 13. Give treatment of tubercular peritonitis. 14. Give diagnosis of lipoma of the neck. 15. Give diagnosis and treatment of aneurysm of the femoral artery.

OBSTETRICS AND GYNECOLOGY

1. What are the characteristics of the female pelvis and how does the male pelvis differ therefrom? 2. Describe the vulva (*a*) of a virgin, (*b*) of a multipara. 3. Describe (1) the process of fecundation, and (2) the uterine changes resultant. 4. Describe pelvimetry and name the five most important measurements. 5. Describe Walcher's posture and its uses. 6. What precaution as to the urine should be employed in the case of a pregnant woman? 7. Differentiate accidental hemorrhage, placenta prævia, postpartum hemorrhage. 8. Describe fully the treatment you would use in postpartum hemorrhage. 9. How should asphyxia neonatorum be managed? 10. Cause, preventative treatment and curative treatment of ophthalmia neonatorum. 11. What causes puerperal infection? How may it be prevented? 12. How do you prepare a patient for an operation which is to involve both the abdominal surface and the vagina? 13. What are the causes of pelvic abscess? Outline treatment. 14. Describe the menopause and name the diseases common to that period of life. 15. Differentiate vaginitis and vaginismus and give treatment of the latter.

MATERIA MEDICA AND THERAPEUTICS

1. What remedies may be used to induce emesis? Give dose of each. 2. Name three mineral acids with therapeutic properties of each. 3. State uses and doses of salol, guiacol and heroin. 4. Give the source and physiological action of opium; name four preparations with adult dose of each. 5. Define alteratives; name five used in medicine with the therapeutic properties of each. 6. Compare the physiological action of aconite and digitalis; give adult dose of each. 7. Describe symptoms of ptomain poisoning; outline the treatment. 8. Differentiate the effects of strychnin, nitroglycerin and strophanthus on the arterial system. 9. Mention three vegetable and three mineral astringents with adult dose of each. 10. Specify the precautions to be used in administering chloroform; give reasons therefor. 11. Diagnosticate uremic poisoning; outline an eliminative treatment. 12. Explain the action and effects of phenacetin; give adult dose. 13. Prescribe in proper form for chronic bronchitis in an adult; explain the action of the ingredients used. (Candidates must not sign name or initials.) 14. Enumerate the official praparations of arsenic; state the dose of each. 15. Give three examples of animal extracts with indications for the use of each.

HYGIENE

1. Define hygiene. 2. What would you advise a person to do that fears pneumonia, rheumatism, nephritis, insomnia? 3. What is absolutely necessary for the maintenance of the healthy functions of the body 4. What is an antiseptic? What is meant by the term disinfection? 5. Name five disinfectants. 6. Why does a heated atmosphere charged with moisture render sunstroke liable? 7. State the time that quarantine should be imposed in (*a*) diphtheria; (*b*) small-pox. 8. What instructions should be given a nurse respecting the prevention of the spread of scarlet fever from the sick room?

MEDICAL JURISPRUDENCE

9. State the difference between criminal and civil malpractice. 10. Name some of the violent causes of death. 11. Give in detail the condition which would warrant the induction of abortion by the practitioner. 12. Define the word "insanity." 13. Name the post-mortem signs external and internal of recent drowning. 14. When is induced abortion lawful and what are the conditions in which it is called for? 15. In a case of suspected infanticide, what are the evidences of live birth?

HOMEOPATHIC MATERIA MEDICA AND THERAPEUTICS

1. Compare arsenic, camphor and ipecac in measles. 2. Compare china, rhus, and bryonia in bilious fever. 3. Compare secale, belladonna, and crocus, in uterine hemorrhage. 4. Compare nitric acid, hepar, and hyoscyamus in cough. 5. Compare phosphorus, arsenic, and antimonium tart., in edema of the lungs. 6. Prescribe for chill and fever, thirst, quick pulse, hot, dry skin, nervous excitement, piercing pains in chest and dry cough. 7. Prescribe for idopathic intercostal neuralgia in anemic subjects, with deranged uterine function. 8. Prescribe for constant thirst, nausea, prostration, burning in stomach, violent belching, vomiting. 9. Prescribe for sick headache from wine, study, sedentary habits, beginning in the morning and increasing all day, worse after eating or from noise. 10. Prescribe for delirium with incoherent muttering, furious, loquacious, small quick pulse, skin cold and clammy. 11. Give treatment for apoplexy. 12. Give treatment for gall-stone colic. 13. Give treatment for mastitis. 14. Give treatment for acute articular rheumatism. 15. Give treatment for earache.

Book Notices

MEDICAL DIAGNOSIS. By W. Mitchell Stevens, M.D., M.R.C.P., Fellow of University College, London. Cloth. Price, 25 shillings net. Pp. 1571, with 177 illustrations. London: H. K. Lewis, 136, Gower St., 1910.

The plan of this book is to give an outline of the symptoms and signs of a disease and then to state under the head of differential diagnosis the other diseases from which, because of close or superficial resemblance, it is to be differentiated. This plan has been consistently carried out and the salient points in medical diagnosis and differential diagnosis are well set forth. It is of value, therefore, to the student who is preparing for examination and who wishes to have these facts in tabular form. It may also prove of service to the physician who, when confronted by a puzzling case, wishes to fortify himself in his tentative diagnosis by excluding other possible confusing diseases. He will here find listed the conditions which might cause error.

There is a lack of consideration of the subject from the standpoint of physiology and pathologic anatomy, which would enable one to see more clearly the reasons for symptoms and signs. The book is too much on the order of the quiz-compend, which has its place, though not a very honorable one. And the same character of the book makes it for the practitioner, while not an unsafe guide, yet one that helps him very little, for it does not make him think and reason enough. Diagnosis should be the result of a logical mental process and not a search through the index to see if perchance the right name may be found.

There are numerous good illustrations. The text is seldom ambiguous; in fact, the sentences, and even paragraphs, are at times little more than lists of symptoms or of diseases. Most of the facts, as stated, are such as one would agree with. In a book of this kind it is inevitable that there should often be omission of what seems to the reader an important symptom—perhaps his pet symptom—or an emphasis laid on what he would regard as a feature of minor importance. But on the whole one can endorse what is said, and the criticism is rather on the plan of the work, as already stated.

HANDBOOK OF DISEASES OF THE EYE. A Text-Book for Students and Practitioners. By Harry Caldwell Parker, M.D., Clinical Professor of Ophthalmology, Indiana University School of Medicine, Indianapolis, Ind. Cloth. Price, $2 net. Pp. 303, with 116 illustrations. Philadelphia: F. A. Davis Co., 1910.

Now that the general practitioner has been urged, in view of the activity of the "doctor of optometry," to inform himself concerning the elements of ophthalmology—and in particular the practice of refraction work so as to be ready to "fit glasses"—one looks with more than ordinary lenience on the multiplication of undergraduate text-books dealing with ophthalmic science. While Parker's manual is no better and no worse than the dozen other compends that are accessible to the student, undergraduate and postgraduate, yet it lacks in the section given over to the determination of the refraction and dismisses in less than thirty pages what might well occupy fifty. Doubtless, this is due to the restricted character of the book; perhaps, after all, the various problems that confront one in "fitting glasses" are not to be solved by reading school-books but by actual practice and instruction in clinics and elsewhere.

Although few of the illustrations are original, they are better than one sees in the average manual of ophthalmic practice. The descriptions of diseases and of operations are, as a rule, lucid and effective.

UNSOUNDNESS OF MIND. By T. S. Clouston, M.D., LL.D., F.R.S.E., Formerly Lecturer on Mental Diseases in the University of Edinburgh. Cloth. Price, $2.50 net. Pp. 360, with 14 illustrations. New York: E. P. Dutton & Co., 1911.

This book was written for the intelligent layman. The author has long been known as England's foremost asylum superintendent, whose writings, especially his clinical lectures on mental diseases, have for many years been considered classic. Having due regard for the difficulties attending the popularization of such an all-embracing subject as that included under the title "Unsoundness of Mind," we think that the author has executed his task most satisfactorily. The book is written in an easy and semipopular style, and the views expressed are in general up to date. In our opinion, not only the layman, but also the busy practitioner, will find something of value in this treatise.

MENTAL MECHANISMS. By William A. White, M.D., Author of "Outlines of Psychiatry," Superintendent Government Hospital for the Insane, Washington, D. C. Nervous and Mental Disease Monograph Series No. 8. Paper. Price, $2. Pp. 151. New York: The Journal of Nervous and Mental Disease Publishing Co., 1911.

In eight chapters, mostly reprints from medical journals in which each chapter had been published as a complete article, the author gives a real insight into Freudian psychology. The author does not merely show the results of Freud's influence—he is entirely submerged in the mental mechanisms of the latter's psychology. Irrespective of the fact that "Mental Mechanisms" contains the views of only one school, and that the youngest and most vehemently opposed, the book is worth reading. The author possesses the happy faculty of being able to restate his teacher's opinions in a more interesting and entertaining style than the teacher himself could bring to bear on the subject.

Medicolegal

Tracing Cause of Cold

(Crawford vs. Maine Central Railroad (N. H.), 78 Atl. R 1073)

The Supreme Court of New Hampshire holds that where there was evidence that a woman's illness which terminated in her death, was a natural and probable result of the condition created by the railroad company's negligent failure to keep one of its stations properly warmed, it was no defense to say that colds are contagious, and that she might have contracted her cold by exposure to contagion as well as from exposure to the low temperature of the station. The difficulty with that contention in this case was that there was no evidence of exposure to contagion; either that colds of any description were generally prevalent, or that any person with whom the woman had come into contact suffered in that way. The only cold in the evidence was the one she had. Whatever the truth may be as a matter of science, there was competent evidence in the case that colds might be produced by such exposure as befell this woman through the company's failure to properly warm the room provided for waiting passengers. The possibility of other sufficient causes of which there was no evidence did not preclude the jury from ascribing the cold to the cause of which there was evidence, if the connection, in the light of all the evidence, appeared to them sufficiently clear and definite. The possibility that something else might have been the primary cause thereof was not an answer as matter of law. It was for the jury to determine *the probable cause on all the evidence. If* a person were at the same time exposed to two sources of contagion equally liable to infect him with disease, whether, if so infected, the infection were due to one cause or the other would be mere speculation or conjecture. But, if there were proof of exposure to one source of infection sufficient to cause the disease, the possibility of other sources of infection, without proof of exposure, would not render the conclusion that the disease was due to the known exposure a guess or conjecture. The latter case would present a question of probability for the jury; the former would not. If the cold in question was a "grip cold," solely due to exposure to a germ, and not due to the exposure in the company's station, it was entirely immaterial where it was contracted.

Death During Administration of Chloroform Accidental—Not *Within Exceptions to Accident Insurance Contract* —"Surgical Treatment"

Beile vs. Travelers' Protective Association (Mo.), 135 S. W. R. 497

The St. Louis Court of Appeals reverses here an order setting aside a verdict for the plaintiff on an accident benefit certificate issued to her husband, who died while chloroform was being administered to him by a physician preparatory to performing a surgical operation on him for fistula, his death occurring after from 20 to 30 drops of the chloroform had fallen on the mask, without having had the knife applied to him and without surgical treatment having been begun, unless administering chloroform was "surgical treatment."

One of the defenses was that the insured did not die by "accident," within the meaning of the contract; but it is held that it was error to hold as a matter of law that the death was not by accident. In order for the dilatation of the heart to have been the natural and probable consequence of the administering of the chloroform, and therefore not an accident, it must have been a result which was expected, or one which ought to have been expected, and this could not be without the insured knew of the defects in his heart and other organs, or they were so apparent to the ordinary powers or means of perception that he ought to have known of them.

Nor does the court consider that it was a defense that the benefit certificate provided that the benefit did not cover injuries "fatal or otherwise, resulting from any poison or infection, or from anything accidentally or otherwise taken, administered, absorbed or inhaled," because the Supreme Court of Missouri has held that "such exceptions do not cover medicine (even though it contain poison) or anything taken or administered in good faith to alleviate physical pain, even though it results in unexpected and unintentional death."

With regard to a special exception of the contract of death caused "wholly or in part by a bodily or mental infirmity or disease," the court thinks this clause meant nothing more than that, in order for the plaintiff to recover, the administering of the chloroform, and not bodily or mental infirmity, must have been the proximate cause of the death.

Lastly, the court is unable to agree with the contention that the death did result from "surgical treatment," within the meaning of another exception of the contract. The court gathers from reading certain definitions that "surgical treatment" means treating a disease or a patient by means of surgery, which in turn means applying manual operations or instrumental appliances to the affected part for the purpose of curing or relieving the bodily disease or ailment. Administering chloroform as was done in this case does not come within any of these definitions or meanings. It was not a manual operation or the application of an instrumental appliance, and was not resorted to as a remedy or for the purpose of curing or relieving the insured's ailment. It was administered as preparatory to the surgical operation; but so might have been his bath, and if he had died in his bath it would not be seriously contended that he died as a result of a surgical treatment. The most that might be claimed for the defendant was that the language of the exception was so vague and general, not identifying the subject-matter, that oral evidence was admissible to identify it, to show just what was comprehended within the term "surgical treatment," and that the jury should have been left to decide the matter as a question of fact. The jury found that "surgical treatment" did not include the administering of chloroform under the circumstances here disclosed, and the court is of the opinion that its finding was in accordance with the usual and ordinary understanding of the term.

Paralysis of Hand is Paralysis of "Either Extremities" and a Permanent and Total Disability

(Brotherhood of Locomotive Firemen and Enginemen vs. Aday (Ark.), 134 S. W. R. 928)

The Supreme Court of Arkansas says that it was contended that if the plaintiff Aday had permanent paralysis of his hand, that it was not "permanent paralysis of either extremities," and that he was not thereby "permanently and totally disabled or incapacitated from performing all manual labor" and entitled to the amount of his beneficiary certificate in the brotherhood. But the extremities of the body are four in number and "either" is one indifferently, any one of them; and the permanent paralysis of a hand resulting from a cut on the arm brought the plaintiff within the meaning of the term "permanent paralysis of either extremities." Moreover, the court can see no difference between the total incapacity of the beneficiary member by the loss of a hand by actual separation and its absolute loss of usefulness by paralysis thereof, and holds that the latter was such a permanent and total disability as was in the contemplation of the parties in the making of this contract. The undisputed testimony showed that his left hand was paralyzed, that the four fingers of it were atrophied or "dead—no feeling in them at all," as he expressed it; that he was unable to grasp anything; that he had very little grip in his thumb, and that his hand was getting worse all the time; and that because of it he was unable to perform, and compelled to retire from, any further railroad service whatever. Two of the three experts employed by the brotherhood to examine him testified that the left hand was paralyzed and the disability permanent, and the other that without an operation it was permanent paralysis; and the proof was undisputed that his condition was such that he could not procure the services of such an eminent specialist as would be able to perform the operation that might result in preventing the disability from continuing permanent. There was no conflict in this testimony. It was undisputed that his left hand was permanently paralyzed, unless, as one expert thought, it might possibly be cured by an operation by such an eminent specialist as the undisputed testimony showed he had no means to employ. Under such circumstances, there was no question for the jury, and the court did not err in directing a verdict in favor of the plaintiff.

Society Proceedings

COMING MEETINGS

American Electro-Therapeutic Association, Philadelphia, Sept. 6-7.
Medical Society of the Missouri Valley, Omaha, Neb., Sept. 7-8.
Washington State Medical Association, Spokane, Sept. 5-7.
Wyoming State Medical Society, Thermopolis, Sept. 4-5.

AMERICAN OPHTHALMOLOGICAL SOCIETY

Forty-Seventh Annual Meeting, held at New London, Conn., July 11-12, 1911

The President, Dr. E. Gruening, New York City, in the Chair

Officers Elected

The officers elected were named in The Journal, August 5, p. 490. The society will meet next year June 11-12, probably at Hot Springs, Va.

Four Cases of Acute Disseminated Myelitis, with Retrobulbar Degeneration of the Optic Nerves

Dr. Ward A. Holden, New York City: All these patients (adults) had sensory disturbances in the trunk and limbs, and more or less complete paraplegia. These conditions continue to the present time in two patients, while the other two are dead of respiratory paralysis. The fields of vision in the three cases in which they could be determined were peculiar. In one there was excessive eccentric contraction of the field with fair central vision, and in two there was hemianopia for certain test objects in one eye alone. No autopsy material was obtained other than a portion of the cervical cord in two cases. Photomicrographs of sections of these cords show characteristic foci of degeneration, and also the arteries, with cellular infiltration about them; running from the uninfiltrated pial sheath to the areas of softening.

A Case of Periodic Fugacious Episcleritis

Dr. Albert C. Snell, Rochester, N. Y.: A woman, 42 years old, had recurring superficial episcleritis at each menstrual epoch. There was a history of attacks extending over a period of five years and still recurring. The season does not appear to have anything to do with the occurrence of attacks.

Serum Treatment of Sympathetic Ophthalmia

Drs. George S. Derby, Boston, and H. N. Pratt, Louisville, Ky.: The patient developed severe uveitis of the right eye following injury to the left. There was no improvement under inunctions and massive doses of salicylate. The injection of serum from a patient recovering from sympathetic disease was followed by marked improvement. A subsequent recurrence necessitated further injections of serum at intervals during eight weeks. The patient was discharged with useful vision. The same procedure was attempted in several other cases with different serums but without marked results.

DISCUSSION

Dr. R. N. Randolph, Baltimore: It really looks as if we had in this serum a powerful remedy for sympathetic ophthalmia, but the difficulty that exists in getting the serum makes it doubtful whether we are justified in changing our attitude toward injured eyes. There are more cases of this disease reported than there used to be and I think that this is largely due to the existence of a more venturesome spirit in treating diseased corneas by means of salicylate of soda. In the cases of children, particularly, I believe that we should take no risk.

Dr. J. H. Claiborne, New York City: Six or eight years ago Dr. E. B. Coburn and I pursued a number of investigations along these lines. The results of these experiments were absolutely negative. Our conclusion was that one cannot influence in rabbits a sympathetic ophthalmia by the injection of a corresponding serum into the venous system.

Dystrophia Epithelialis Corneæ (Fuchs); Report of a Case

Dr. Arnold Knapp, New York City: My patient was a woman, aged 81, who, after a successful cataract operation, without signs of inflammation or glaucoma, developed these curious corneal changes. The other eye was operated on twelve years ago and presents similar, but more pronounced, changes in the cornea.

A Protest Against the Indiscriminate Use of the Organic Compounds of Silver in Ophthalmic Practice

Dr. Samuel Theobald, Baltimore: These compounds are unquestionably more liable to produce conjunctival argyria than is silver nitrate. Before their introduction, this was a rare condition, being practically never seen except in old cases of trachoma. Now it is relatively common. For this reason, they should not be used when other remedies are really efficacious. An observance of this rule would very nearly limit their employment to gonorrheal and trachomatous conjunctivitis. Especially are they contra-indicated in catarrhal conjunctivitis, in which they are now so generally prescribed, because in a collyrium of zinc sulphate and boric acid we have a remedy that is more surely and promptly efficacious.

DISCUSSION

Dr. Lucien Howe, Buffalo, N. Y.: A very excellent report on this subject was made by a committee of the Section of Ophthalmology of the British Medical Association. It contained the statement that the proportions of silver in these compounds vary greatly. If they are as efficacious as some think, this is evidently not due to the amount of silver that they contain. Before adding to the amount of advertising that we have given to various proprietary compounds, it would be well for us to examine our records to see whether we do get the results that we think we get from them and whether we could not obtain as good results from some other remedies that we have known of for a long time.

Dr. Alexander Duane, New York City: The only antiseptic that has a practical value in the limits of time that a solution in the eye can act is nitrate of silver. Therefore, we are thrown back on detergent solutions. In this capacity some of the silver compounds have an important value.

Dr. Walter B. Johnson, Paterson, N. J.: In employing nitrate of silver, one knows the strength of the solution in each instance, and there is very little danger of argyrosis. These proprietary medicines are not what we have been led to believe they are.

Excision of the Tarsus and Conjunctiva (Heisrath) in Old Trachoma

Dr. J. H. Claiborne, New York City: Expression has been considered as indicated for trachoma in the florid stage and for trachoma that is marked by cicatrization with abundant granulation. In the latter stages of the disease, however, the results of expression are disappointing. In the first patient, the result of the more radical procedure in both eyes was an entire cure. The result was the same in other cases. I consider this operation indicated in all cases of trachoma in which cicatrization has commenced, and in which pannus and keratitis are present. It should be done, however, only as a last resort. In cases in which expression will answer, this should be employed. My experience convinces me that the tarsal cartilage in a cicatricial state is the cause of all our woe in old trachoma. In the operation as performed by me, the hands of the operating surgeon alone are around the eye. The clamp used is the result of a number of experiments. The operation is practically bloodless, and can be done in from ten to fifteen minutes, thus differing from other methods.

A Case of Ring Sarcoma of the Ciliary Body

Dr. A. N. Alling, New Haven, Conn.: The region of the ciliary body was occupied by a flat, black, slightly prominent mass, which in part involved the iris, and at several points extended through the sclera, forming irregularly rounded prominences on the anterior surface. The growth was a sarcoma, composed of large endothelium-like cells and spindle cells.

DISCUSSION

Dr. E. Fuchs, Vienna, Austria: I have seen four cases of ring sarcoma, in all of which the eye showed merely a swollen condition and a changed color. It is often impossible to make the diagnosis of sarcoma in these cases, because one finds the eye too intensely fixed.

April

1 *Action of Tropical Sun on Men and Animals. H. Aron.
2 *Eradication of Beriberi From the Philippine (Native) Scouts by Means of a Simple Change in Their Dietary. W. P. Chamberlain.
3 *Case of Dysentery Caused by Balantidium Coli with Coincident Filarial Infarction of the Spleen. F. B. Bowman.
4 Some Observations on So-Called Flagellates, Ciliates and Other Protozoa Encountered in Water and in Human Stools. E. H. Ruediger.

1. **Action of Tropical Sun.**—Experimental research by Aron showed that under climatic conditions, even during the cooler seasons of the year in Manila, animals, such as rabbits and monkeys, which by nature have only a limited power of physical heat regulation, or animals the physical heat regulation of which is artificially inhibited (tracheotomized dogs) die if exposed to the sun, the body temperature rising to febrile heights. If the same animals are protected from the rays of the sun, or if the increase of heat due to radiation from the sun is compensated by an increased loss such as would be brought about by a strong wind, then the animals suffer no discomfort. Insolation of the skull alone is without effect if the body temperature is kept within normal limits. The postmortem findings on the animals dying as a result of insolation show decided hemorrhagic lesions of the meninges in the brain, and in monkeys, in the heart. In animals without sweat glands the subcutaneous tissues are heated by the radiated heat from the sun to temperatures above those compatible with life. The human skin if exposed to the sun is warmed to about 3 to 4 C. above the normal skin temperature. An increase, even to the normal body temperature, is prevented by evaporation of sweat. The cooling effect of the sweat secretion causes a fall of the skin temperature even if insolation is continued during longer periods. The brown skin of Malays, while theoretically absorbing more heat in the sun, shows a smaller rise in temperature in the tropical sun than the skin of white men under similar conditions. As an explanation, it is believed that an earlier and better water evaporation by sweat secretion takes place. The air in the human hair, especially in black hair, under the influence of the tropical sun acquires temperatures far above those compatible with life It was demonstrated by Aron that in the tropical sun a man with a colored skin is in a better position as regards heat regulation than is a man with a white skin.

2. **Eradication of Beriberi.**—The real factors in the eradication of beriberi from the Scout organizations have been a reduction in the amount of rice consumed and the addition of a legumen. The result was accomplished without the use of undermilled rice.

3. **Dysentery Caused by Balantidium Coli.**—During the past three years Bowman has seen ten cases of infection with *Balantidium coli*. Two of the ten cases terminated fatally, but the others have had no symptoms other than an occasional diarrhea. Even in the severe infections, the diarrhea was more or less intermittent in character, the parasites being found in the feces only during these attacks. This phenomenon is explained by Bowman in the following manner: The organisms, moving along in the submucosa, become so numerous as sometimes to form "nests" from which low inflammations develop, and which, proceeding to ulceration, cause erosion of the mucosa and set free the balantidia. At this time the organisms are found in the feces. In some areas the blood-vessels appear practically to be occluded by the number of balantidia present and this fact in itself is sufficient to initiate an inflammatory process by lowering the tissue resistance.

6. **Surgical Treatment of Amebiasis.**—The surgical treatment of intestinal amebiasis is advocated by Seaman. It is simple, free from danger and not beyond the skill of a surgeon of reasonable ability. It should, therefore, be maturely considered whenever a fair trial of other procedures has lead to no improvement of the patient's condition. Medical treatment and intestinal lavage *per vias naturales* is often unproductive of benefit.

16. **Larval Hyperacidity.**—Friedenwald's observations with this condition extend over a series of six cases. Of these, there are four males and two females. The ages vary between 26 and 58 years. The symptoms are largely those of a neurasthenia, evincing at the same time special manifestations of hyperchlorhydria, consisting of pain and pressure in the region of the stomach one hour after meals, and extending over a period of from one to one and one-half hours, and usually relieved at the end of this time, or at any time, by the ingestion of food. Acid eructations, nausea and occasionally vomiting of acid material are most prominent. The appetite is usually increased, though on account of the pain induced by the ingestion of food there is usually fear of eating. In not one of Friedenwald's cases could an epigastric painful area be detected, and occult blood was always absent in both gastric contents and in the stools. In all instances general nervous symptoms were manifested, as headaches, insomnia, lassitude, irritability and depression, with periods of discomfort alternating with accountable periods of well-being, the periods of discomfort often being induced by nervous influences, such as shock or anxiety. The quantity of gastric contents obtained is always large, varying between 214 and 368 c.c., always a most significant feature of this condition. The appearance of the contents is also characteristic, consisting largely of a watery secretion containing but little sediment. On standing, two layers are formed—a lower, slight in amount, but with solid sediment, and above a clear layer, larger in quantity. After centrifugalization the amount of solid sediment in proportion to the total sediment is constantly under 22 per cent., while the fluid content ranges as high as 90 per cent. Under normal conditions the amount of the solid sediment is as 40 to 60 to the total sediment; the variation from the normal is an additional evidence, therefore, of the presence of larval hyperacidity. The specific gravity of the gastric secretion varies between 1010 and 1014, reduced from the normal of between 1015 and 1020. The total acidity as well as the percentage of free hydrochloric acid is always normal, the former varying between 38 and 56, the latter between 30 and 44, though in the earlier period of digestion a high total acidity as well as a marked hyperchlorhydria is always manifested. The amidulin reaction is present in all instances. Numerous examinations were made on all the patients.

The treatment of the condition should be largely directed toward the management of the nervous system. In emaciated individuals the best results are obtained by means of a systematic rest-cure treatment. The diet should consist largely of three meals a day, together with intermediate feedings of liquid food. The dietary should contain an excess of proteids and fats, and but a moderate quantity of carbohydrates. Of the various proteid foods, milk, eggs and fish are to be preferred. Fats have a tendency to decrease the gastric hyperacidity, and are to be recommended. Of these, butter, cream and olive oil are especially useful. The carbohydrates are only permissible in the most digestible forms, and vegetables should be mashed and strained and taken in the puree form, free of all cellulose. Water is usually well borne, and may be administered in large quantities with benefit. All acid food, as well as stimulants, should be avoided. The alkalies, together with belladonna, are of great service in the treatment of this disorder. Good results are usually obtained from the use of hydropathic measures, as well as from massage.

17. **Amyotonia Congenita.**—From a review of the few cases yet reported with necropsy, the authors conclude that in the lighter cases the alteration may be confined to the muscles, and possibly, therefore, the disease is primarily muscular, but this inference is not fully warranted. In the intense cases the nervous system is affected in marked degree. The relations to muscular dystrophy are as yet undetermined. The points of resemblance to both these diseases cannot be ignored.

18. **Toxic Actions of Digitalis.**—The observations on which Bailey's paper is based were made on ninety patients under treatment with digitalis or digitalis bodies. The administration of the digitalis to these patients was conducted with great care, and improvement in the character and condition of the pulse, with relief from the symptoms, was the accepted indication for either stopping the drug or reducing the dosage. About 25 per cent. of the patients showed some form of toxic action. These observations were made during the course of another research, and many of them do not cover the entire period of the toxic action. Bailey says that the toxic effects of digitalis and related bodies may be divided into three periods with regard to their occurrence and severity. These toxic symptoms may usually be discovered in their earliest stages by careful and frequent sphygmographic observations. (1) Period of vagus stimulation; (2) period of depression of conductivity with masked vagus action; (3) period of marked muscular irritability with depression of contractility. Digitalis heart-block may be differentiated from ordinary heart-block and from vagus influence as a causative factor. Muscular irritability may be the first symptom observed, the other stages being short in duration and easily overlooked. Irritability from digitalis must be differentiated from the progress of the disease by careful observations of the different functions as evidenced by combined tracings. With therapeutic doses the rise of blood-pressure due to vasoconstriction is so slight that it may be disregarded, but with toxic doses it becomes of extreme importance. Cumulation occurs with digitalis and may last for a considerable period. Vomiting is probably a central effect of digitalis and is a *sign that* absorption is occurring. Pulsus alternans may be relieved by digitalis in some cases.

19. **Acute Infectious Disease of Unknown Origin.**—To supplement the clinical study of an acute infectious disease of unknown origin, which was published in the *American Journal Medical Sciences* for April, 1910, and abstracted in THE JOURNAL, April 30, 1910, p. 1476, Brill records his observation of a fatal case of the disease. This case opened the way to supply the lacking necessary pathologic data which would carry the study nearer completion, and at the same time to furnish additional evidence that the disease has no relationship with any of the typhoidal group infections. A solution

of the mystery, of what the disease really is; is no nearer completion than before. From this report the conclusions may be reached that the organs showed congestion and general parenchymatous degeneration such as would obtain in any intense infectious disease. It is noteworthy, in consideration of the fact that many believe this disease to belong to the typhoidal group infections, that the intestines showed none of the lesions which are characteristic of typhoid. The presence of *Staphylococcus albus* and *S. citreus* and unidentified bacilli, Brill believes, were most probably due to agonal or post-mortem invasion, and were non-pathogenic. The appearance of the patient on the last day of her illness was the clinical picture of coma, petechial eruption, carphology, paralysis of the sphincters and the rapid elimination of the heart action.

20. Abstracted in The Journal, August 12, 1911, p. 591.

23. **Ascitic Fluid for Nutritive and Therapeutic Purposes.**—The ascitic fluid used by Carter in these experiments was obtained from patients with cirrhosis of the liver, free from toxemia of any kind. The nitrogen content should be determined, as this is found to vary within fairly wide limits, 0.17 per cent. to 1 per cent. of nitrogen or more (blood-serum contains about 1 per cent. of nitrogen), and first tappings are apt to be higher in nitrogen content than subsequent ones from the same case. A few important points have been suggested by Carter's experiments on two dogs. In both instances the dogs remained well throughout the experiment, and showed no evidences of serum sickness, except when on large amounts of serum they were occasionally a little less lively, when also a transient edema about the site of injection might occasionally be seen for a few hours; this was, however, an exception. Carter says that it is apparently not advisable to attempt to give the full protein requirement by hypodermic, particularly if the nitrogen content of the fluid is low, as it necessitates injecting excessive volumes of serum, and under such circumstances a considerable portion of the liquid may be retained in the tissues as edema, and the urine temporarily decreased in amount, thus interfering, for a time, with the necessary elimination of toxins in an infection. While apparently the excessive volumes do not cause a true nephritis, it is, nevertheless, a serious matter to hamper the filtration power of the kidneys. This does not take place when moderate amounts are given for short periods. It is quite essential to give a fair amount of extra water to the system during the use of the hypodermic method, either by the mouth, rectum or hypodermically. It is best to begin with a single moderate dose and gradually increase to two doses daily, twelve hours apart, the actual amount depending on the nitrogen content of the fluid.

Judging from a limited clinical experience, Carter is led to believe that probably one or two doses only may be required to bridge over a desperate period. Probably also the daily dosage should not exceed 10 c.c. to 15 c.c. per kilo, depending on the nitrogen content. For any possible stimulating effect on growth (as in marasmus) the dose should be small, perhaps 2 to 10 c.c. per day. The theoretical indications for its use are suggested as follows: 1. In any condition in which there is need of protein which the organism cannot make use of when given in the ordinary way as food, but probably only for a short time. 2. In conditions in which the tissues are, so to speak, dried out; the percentage of fluid in the organs being lowered, as in intractable vomiting, diarrhea (acute), gastro-enteritis, in children especially, cholera, etc. 3. When the organism is being overdone by an infection for which we have not a specific antitoxin. 4. When for some reason the growth of the body is interfered with by unknown causes, as in marasmus. 5. In blood conditions, such as hemophilia, hemorrhage, melena neonatorum, where the hypodermic use of normal human serum has already been shown to be valuable, with the added advantage that ascitic fluid is easily obtained in large quantities.

In order to demonstrate any possible usefulness of ascitic fluid as a food when given by the hypodermic route, a series of nine children (eight suffering from the most extreme grade of acute gastro-enteritis or enterocolitis, and one from bronchopneumonia and enteritis) were treated by this method. It was thought best to use it only in patients who had been treated unsuccessfully by the usual methods, and which, consequently, were in the terminal stages of the disease, in order that the test should be the most severe; so too that any improvement might, perhaps, fairly and justly be attributed to the treatment under trial. The plan adopted was to give one injection and to watch the results, stopping at that point if definite improvement was shown. When the improvement was not so marked, repeated doses were given daily in increasing amounts. The nitrogen content of the fluids used varied from 0.34 to 0.4 per cent. nitrogen. Of the nine patients treated, two recovered absolutely, and one showed almost immediate improvement, which lasted for a week, at the end of which the child died, although the improvement had been continuous up to the day of death and the patient actually gaining in weight. No discoverable cause of death was found post mortem, although the autopsy was not done by an expert pathologist. In all three cases the action of the ascitic fluid was apparently perfectly definite, and showed itself within a few hours of the time of injection. Even allowing that only two patients were helped, a percentage of 22 per cent. possibly cured in the face of such desperate conditions as existed in all these cases makes it at least worth further investigation.

33. Abstracted in The Journal, June 3, 1911, p. 1676.

34. **Treatment of Chronic Universal Perihepatitis.**—After considerable study, and more experimentation, it was found that antipyrin salicylate, in 10-grain doses, given every two to four hours, would relieve the symptoms and limit the duration of the exacerbations to a very few days or sometimes hours. Usually at the expiration of thirty hours the patient regains his normal condition.

35. **Physician and Infant Mortality.**—To remove from an annual loss of 150,000 deaths in the United States among infants under 1 year those deaths which are preventable, Newmayer says, requires the state and municipal authorities to educate the poor in the proper care of infants and the hospitals furnishing sufficient and intelligent medical and nursing care of the sick infant. There is also required of the medical profession a similar responsibility to those who can afford to pay for and need such medical service.

39. **Action of Animal Extracts on Bladder.**—In the experiments conducted by Ott and Scott on the exposed bladder of forty-five cats it was observed that thyroid extract produced strong contractions of the bladder, with the pelvic nerves intact. Prostate (¼ to 1 grain) increased the contractions of the bladder and also augmented their frequency. Parathyroid (½ grain) increased the tonus and height of contractions of the bladder. Epinephrin relaxed the bladder. Mammary gland (½ to 1 grain) had no action on the bladder. Pancreas (1 to 2 grains) produced strong contractions of the

bladder; in one case it caused a tetanic contraction four days after section of the nervi pelvici. Ovary (½ grain) increased the contractions of the bladder to a slight extent. Orchitic extract increased the contractions. Parotid (1 grain) considerably increased the extent and frequency of the contractions. Thymus (½ grain) increased the extent of the contractions. Brain extract increased the extent of the contractions.

48. **Surgical Treatment of Spina Bifida.**—In the operation employed successfully in four cases by Babcock the edge of the dura where it blends with the inner surface of the lamina is incised on either side and stripped from the bony canal for the entire distance of the defect. The dura is then sutured over the cord by a continuous fine chromicized catgut suture, thus restoring the dural canal. The margins of the bony canal are freely exposed and with a pair of Satterlee's bone forceps the laminæ are divided the entire length of the defect. This is repeated on the opposite side, forming two ribbons of bone and fibrous tissue, each consisting of a chain of imperfect spinous processes and laminæ, having attachments above and below. These bony bridges are then united to the median line by sutures of chromicized catgut, thus restoring the bony canal and the position of the rudimentary spinous processes. A knife is then passed through the erectorspinæ group of muscles, splitting off on either side a broad strip of muscle with its overlying aponeurosis. This likewise is left attached above and below and these two musculo-aponeurotic bridges are slid to the median line reinforcing the bony canal. Thus there is placed immediately over the cleft a solid mass of firm tissue.

66. **Interlobar Exudates.**—The signs of an encapsulated interlobar exudate of considerable size as enumerated by Stone are: A zone of dulness, more or less high pitched and tympanitic in character, with presence of bronchovesicular breathing over the dull area, often accompanied with friction sounds, if the condition is acute; below the dull zone the resonance and respiratory sounds are more nearly normal; on the left the tympanitic area of the stomach (Traube's space) is retained and on full inspiration the more normal area below the zone of dulness increases in size; the dull triangle, the paravertebral triangle, in the opposite thoracic cavity is not present as is usual in large, free exudates. If the exudate is on the right side, the heart is apt to be extremely displaced to the left (A. Fraenkel); if on the left, the displacement is not so marked as with free fluid (Stone); the radiograph will show a shadow extending from the apex of the heart towards the head of the humerus, or from the sternal junction of the fourth rib on the right outward to the head of the humerus; the fluoroscope will show the same shadow band and also the diaphragm in motion.

If the exudates are serous, they can entirely disappear, as can other serous exudates in the chest or abdominal cavity. The small interlobar exudates which come to clinical notice are practically all purulent. After severe pleuritis usually accompanying a pneumonia, small encapsulated collections of fluid are left in depressions along the sulci between the lobes. These are frequently infected with the offending organism and become purulent. Such collections of pus, of a tablespoonful or two, are to be found by careful percussion and by the presence of tender spots. Remembering the lines of the interlobar spaces, one presses in each intercostal space with the tip of the finger along these lines, until a tender spot is discovered. This and the percussion note and the exploring needle will usually serve to locate the small empyema immediately beneath the thoracic wall. Similar inclusions of exudate take place between the lobes of the lung during the course of a pneumonia. They become infected and consequently purulent. Very frequently these small interlobar collections of pus become foul and gangrenous and empty themselves spontaneously through the bronchi, and they frequently are considered as lung abscesses, and for the most part very properly belong in that category.

One of the practical conclusions that one comes to after experience and study of thoracic exudates is that, if a short exploring needle does not find fluid, the concealed exudate is usually in the interlobar spaces surrounded by lung tissue and the needle will have to penetrate this lung tissue in order to reach the exudate. Therefore, one should consider carefully the dangers of lung infection from the needle which may possibly be dipped in pus in the cavity which it enters. If it seems necessary to use the long needle, it is to be borne in mind that the axillary region, a little below the normal position of the interlobar sulcus, is to be chosen as the most probable place for immediately entering the cavity and that here the intervening layer of lung tissue will have the least thickness. The same region is likewise the point of election for the removal of ribs and the exploration of the interlobar spaces.

67. **Hemolytic Skin Reaction in Carcinoma.**—This paper is an analysis of the results obtained from a series of 100 patients on whom skin reaction test used by Elsberg for the diagnosis of carcinoma was done. The technic used by Elsberg was followed in every detail in order that the results might be thoroughly reliable. It consists, in general, in injecting 5 minims of a 20 per cent. solution of washed normal red corpuscles into the subcutaneous tissue of the forearm of the patient. Within from three to twelve hours a definite reaction takes place, which is evidenced by the appearance of a slightly raised, slightly tender area about 2 by 3 cm. in area, which takes on a slightly brownish tinge, which may change to a maroon or a dirty greenish-yellow. This lasts eight to

of the mystery, of what the disease really is, is no nearer completion than before. From this report the conclusions may be reached that the organs showed congestion and general parenchymatous degeneration such as would obtain in any intense infectious disease. It is noteworthy, in consideration of the fact that many believe this disease to belong to the typhoidal group infections, that the intestines showed none of the lesions which are characteristic of typhoid. The presence of *Staphylococcus albus* and *S. citreus* and unidentified bacilli, Brill believes, were most probably due to agonal or post-mortem invasion, and were non-pathogenic. The appearance of the patient on the last day of her illness was the clinical picture of coma, petechial eruption, carphology, paralysis of the sphincters and the rapid elimination of the heart action.

20. Abstracted in The Journal, August 12, 1911, p. 591.

23. **Ascitic Fluid for Nutritive and Therapeutic Purposes.**—The ascitic fluid used by Carter in these experiments was obtained from patients with cirrhosis of the liver, free from toxemia of any kind. The nitrogen content should be determined, as this is found to vary within fairly wide limits, 0.17 per cent. to 1 per cent. of nitrogen or more (blood-serum contains about 1 per cent. of nitrogen), and first tappings are apt to be higher in nitrogen content than subsequent ones from the same case. A few important points have been suggested by Carter's experiments on two dogs. In both instances the dogs remained well throughout the experiment, and showed no evidences of serum sickness, except when on large amounts of serum they were occasionally a little less lively, when also a transient edema about the site of injection might occasionally be seen for a few hours; this was, however, an exception. Carter says that it is apparently not advisable to attempt to give the full protein requirement by hypodermic, particularly if the nitrogen content of the fluid is low, as it necessitates injecting excessive volumes of serum, and under such circumstances a considerable portion of the liquid may be retained in the tissues as edema, and the urine temporarily decreased in amount, thus interfering, for a time, with the necessary elimination of toxins in an infection. While apparently the excessive volumes do not cause a true nephritis, it is, nevertheless, a serious matter to hamper the filtration power of the kidneys. This does not take place when moderate amounts are given for short periods. It is quite essential to give a fair amount of extra water to the system during the use of the hypodermic method, either by the mouth, rectum or hypodermically. It is best to begin with a single moderate dose and gradually increase to two doses daily, twelve hours apart, the actual amount depending on the nitrogen content of the fluid.

Judging from a limited clinical experience, Carter is led to believe that probably one or two doses only may be required to bridge over a desperate period. Probably also the daily dosage should not exceed 10 c.c. to 15 c.c. per kilo, depending on the nitrogen content. For any possible stimulating effect on growth (as in marasmus) the dose should be small, perhaps 2 to 10 c.c. per day. The theoretical indications for its use are suggested as follows: 1. In any condition in which there is need of protein which the organism cannot make use of when given in the ordinary way as food, but probably only for a short time. 2. In conditions in which the tissues are, so to speak, dried out; the percentage of fluid in the organs being lowered, as in intractable vomiting, diarrhea (acute), gastro-enteritis, in children especially, cholera, etc. 3. When the organism is being overdone by an infection for which we have not a specific antitoxin. 4. When for some reason the growth of the body is interfered with by unknown causes, as in marasmus. 5. In blood conditions, such as hemophilia, hemorrhage, melena neonatorum, where the hypodermic use of normal human serum has already been shown to be valuable, with the added advantage that ascitic fluid is easily obtained in large quantities.

In order to demonstrate any possible usefulness of ascitic fluid as a food when given by the hypodermic route, a series of nine children (eight suffering from the most extreme grade of acute gastro-enteritis or enterocolitis, and one from bronchopneumonia and enteritis) were treated by this method. It was thought best to use it only in patients who had been treated unsuccessfully by the usual methods, and which, consequently, were in the terminal stages of the disease, in order that the test should be the most severe; so too that any improvement might, perhaps, fairly and justly be attributed to the treatment under trial. The plan adopted was to give one injection and to watch the results, stopping at that point if definite improvement was shown. When the improvement was not so marked, repeated doses were given daily in increasing amounts. The nitrogen content of the fluids used varied from 0.34 to 0.4 per cent. nitrogen. Of the nine patients treated, two recovered absolutely, and one showed almost immediate improvement, which lasted for a week, at the end of which the child died, although the improvement had been continuous up to the day of death and the patient actually gaining in weight. No discoverable cause of death was found post mortem, although the autopsy was not done by an expert pathologist. In all three cases the action of the ascitic fluid was apparently perfectly definite, and showed itself within a few hours of the time of injection. Even allowing that only two patients were helped, a percentage of 22 per cent. possibly cured in the face of such desperate conditions as existed in all these cases makes it at least worth further investigation.

33. Abstracted in The Journal, June 3, 1911, p. 1676.

34. **Treatment of Chronic Universal Perihepatitis.**—After considerable study, and more experimentation, it was found that antipyrin salicylate, in 10-grain doses, given every two to four hours, would relieve the symptoms and limit the duration of the exacerbations to a very few days or sometimes hours. Usually at the expiration of thirty hours the patient regains his normal condition.

35. **Physician and Infant Mortality.**—To remove from an annual loss of 150,000 deaths in the United States among infants under 1 year those deaths which are preventable, Newmayer says, requires the state and municipal authorities to educate the poor in the proper care of infants and the hospitals furnishing sufficient and intelligent medical and nursing care of the sick infant. There is also required of the medical profession a similar responsibility to those who can afford to pay for and need such medical service.

39. **Action of Animal Extracts on Bladder.**—In the experiments conducted by Ott and Scott on the exposed bladder of forty-five cats it was observed that thyroid extract produced strong contractions of the bladder, with the pelvic nerves intact. Prostate (¼ to 1 grain) increased the contractions of the bladder and also augmented their frequency. Parathyroid (½ grain) increased the tonus and height of contractions of the bladder. Epinephrin relaxed the bladder. Mammary gland (½ to 1 grain) had no action on the bladder. Pancreas (1 to 2 grains) produced strong contractions of the

bladder; in one case it caused a tetanic contraction four days after section of the nervi pelvici. Ovary (½ grain) increased the contractions of the bladder to a slight extent. Orchitic extract increased the contractions. Parotid (1 grain) considerably increased the extent and frequency of the contractions. Thymus (½ grain) increased the extent of the contractions. Brain extract increased the extent of the contractions.

48. Surgical Treatment of Spina Bifida.—In the operation employed successfully in four cases by Babcock the edge of the dura where it blends with the inner surface of the lamina is incised on either side and stripped from the bony canal for the entire distance of the defect. The dura is then sutured over the cord by a continuous fine chromicized catgut suture, thus restoring the dural canal. The margins of the bony canal are freely exposed and with a pair of Satterlee's bone forceps the laminæ are divided the entire length of the defect. This is repeated on the opposite side, forming two ribbons of bone and fibrous tissue, each consisting of a chain of imperfect spinous processes and laminæ, having attachments above and below. These bony bridges are then united to the median line by sutures of chromicized catgut, thus restoring the bony canal and the position of the rudimentary spinous processes. A knife is then passed through the erectorspinæ group of muscles, splitting off on either side a broad strip of muscle with its overlying aponeurosis. This likewise is left attached above and below and these two musculo-aponeurotic bridges are slid to the median line reinforcing the bony canal. Thus there is placed immediately over the cleft a solid mass of firm tissue.

66. Interlobar Exudates.—The signs of an encapsulated interlobar exudate of considerable size as enumerated by Stone are: A zone of dulness, more or less high pitched and tympanitic in character, with presence of bronchovesicular breathing over the dull area, often accompanied with friction sounds, if the condition is acute; below the dull zone the resonance and respiratory sounds are more nearly normal; on the left the tympanitic area of the stomach (Traube's space) is retained and on full inspiration the more normal area below the zone of dulness increases in size; the dull triangle, the paravertebral triangle, in the opposite thoracic cavity is not present as is usual in large, free exudates. If the exudate is on the right side, the heart is apt to be extremely displaced to the left (A. Fraenkel); if on the left, the displacement is not so marked as with free fluid (Stone); the radiograph will show a shadow extending from the apex of the heart towards the head of the humerus, or from the sternal junction of the fourth rib on the right outward to the head of the humerus: the fluoroscope will show the same shadow band and also the diaphragm in motion.

If the exudates are serous, they can entirely disappear, as can other serous exudates in the chest or abdominal cavity. The small interlobar exudates which come to clinical notice practically all purulent. After severe pleuritis usually [illegible] panying a pneumonia, small encapsulated collectio[illegible] lobes. are left in depressions along the sulci betwe[illegible] organism These are frequently infected with the off[illegible] of a table- and become purulent. Such collections [illegible]rcussion and by spoonful or two, are to be found by car[illegible]ing the lines of the the presence of tender spots. Rem[illegible] intercostal space with interlobar spaces, one presses in[illegible]ines, until a tender spot is the tip of the finger along th[illegible]rcussion note and the exploring discovered. This and th[illegible] to locate the small empyema imme- needle will usually [illegible]rve to locate thoracic wall. Similar inclusions of exu- diately beneath the [illegible] place between the lobes of the lung during the date tak[illegible] course of a pneumonia. They become infected and consequently purulent. Very frequently these small interlobar collections of pus become foul and gangrenous and empty themselves spontaneously through the bronchi, and they frequently are considered as lung abscesses, and for the most part very properly belong in that category.

One of the practical conclusions that one comes to after experience and study of thoracic exudates is that, if a short exploring needle does not find fluid, the concealed exudate is usually in the interlobar spaces surrounded by lung tissue and the needle will have to penetrate this lung tissue in order to reach the exudate. Therefore, one should consider carefully the danger of lung infection from the needle which may possibly be dipped in pus in the cavity which it enters. If it seems necessary to use the long needle, it is to be borne in mind that the axillary region, a little below the normal position of the interlobar sulcus, is to be chosen as the most probable place for immediately entering the cavity and that here the intervening layer of lung tissue will have the least thickness. The same region is likewise the point of election for the removal of ribs and the exploration of the interlobar spaces.

67. Hemolytic Skin Reaction in Carcinoma.—This paper is an analysis of the results obtained from a series of 100 patients on whom skin reaction test used by Elsberg for the diagnosis of carcinoma was done. The technic used by Elsberg was followed in every detail in order that the results might be thoroughly reliable. It consists, in general, in injecting 5 minims of a 20 per cent. solution of washed normal red corpuscles into the subcutaneous tissue of the forearm of the patient. Within from three to twelve hours a definite reaction takes place, which is evidenced by the appearance of a slightly raised, slightly tender area about 2 by 3 cm. in area, which takes on a slightly brownish tinge, which may change to a maroon or a dirty greenish-yellow. This lasts eight to

108. **Stereoscopic Roentgenography of Chest.**—The object of this paper is to call attention to the principles and technic of stereoscopic *x*-ray examinations, and to describe the alterations in the normal chest shadows, which the authors believe to be characteristic of pulmonary tuberculosis. The shadows within the chest cavity are divided into three main groups: first, the "heavy central shadow," extending irregularly from the upper boundary of the chest cavity to the diaphragm; second, the "hilus shadow," radiating irregularly to a distance of four or five centimeters on either side of the fifth, sixth and seventh dorsal vertebræ; and third, the "linear markings" seen in the lung fields. The "heavy central shadow" is cast by the vertebræ and the mediastinal contents; the heart, aorta and other large vessels, trachea, esophagus, lymphatics and connective tissue. The hilus shadow is cast by the primary branches of the pulmonary vessels with their contained blood, the walls of the primary bronchi, and the lymphatic and fibrous tissue surrounding these structures. The shadows in the lung fields are subdivided into two groups; the heavy trunks and the fine linear markings. The heavy trunks are the shadows of the large branches distributed to separate lobes of the lung, the linear markings are the shadows cast by the smaller branches distributed to the various lobules of the separate lobes. In cases of pulmonary tuberculosis, changes are noted in the hilus shadow, the heavy trunks and especially in the linear markings. The hilus shadow shows usually an irregular increase in area and density with here and there small irregular shadows of very marked density. These bright areas of great density are due to the presence in the chest of calcified caseous or fibrous glands, while the increased area and density of the hilus shadow is due to a general increase in the fibrous and lymphatic tissue which accompanies a local or general mediastinitis. Such changes alone are regarded by the authors as of very slight diagnostic value as regards the presence of active tuberculosis, since other infections may produce the mediastinal changes and the calcified glands, although probably of tuberculous origin, indicate an old process more or less healed. In fact the presence of calcified glands, the other conditions being favorable, may be taken as a good prognostic sign. The heavy trunks extending toward the involved area usually appear broader, denser and less regular in outline than in the normal. Here again this change in the heavy trunks is not necessarily tuberculous in origin, so that too great importance must not be attached to this change alone. The fine linear markings appear broader, denser and less regular in outline, frequently their course is studded, sometimes almost to obliteration of the lines; they appear to cross and interweave, producing a delicate network of varying-sized mesh. The anatomic explanation of this altered shadow picture the authors are not at this time ready to discuss, but they firmly believe that the increase in the hilus shadow, the thickening of the trunks, together with the alterations in the linear markings, increase in density and breadth, studding, interweaving and extension to the periphery, constitute a shadow picture characteristic of early pulmonary tuberculosis. As the lesion progresses the alterations become more marked; the linear markings are more and more broken up and irregular, the studdings become larger and denser and the interweaving closer, until eventually the whole area appears as a more or less homogeneous shadow of increased density, due to the presence of gross areas of consolidation within the lung.

109. **Paroxysmal Hemoglobinuria.**—The serum of patients suffering from paroxysmal hemoglobinuria, Moss found, contains a complex hemolysin, of amboceptor-complement nature, which is capable of bringing about the solution of the patient's own corpuscles, corpuscles of other paroxysmal hemoglobinuric patients, and of all other individuals, as far as tested. Patients suffering from paroxysmal hemoglobinuria are not confined to one group, as determined by the iso-agglutination reaction, and their serum may contain normal isohemolysin in addition to the hemolysin characteristic of their disease. The auto-amboceptor may be absorbed from patient's serum, leaving the iso-amboceptor and conversely the iso-amboceptor may be absorbed, leaving the auto-amboceptor, thus enabling each to be tested separately on any given set of corpuscles. Only the amboceptor component of the hemolysin of paroxysmal hemoglobinuria is peculiar to the disease. The complement differs in no way, so far as tested, from that present in normal serum. The amboceptor peculiar to paroxysmal hemoglobinuria differs from other known hemolytic amboceptors in that it will unite with the red blood-corpuscles only at a low temperature in the presence of complement, and furthermore, in that it is capable of bringing about the solution of the patient's own cells (auto-hemolytic action) and those of other members of the group to which the patient belongs, as well as the cells of members of other groups. Hemolysis due to the autohemolysin of paroxysmal hemoglobinuria, unlike normal isohemolysis, may occur entirely independently of agglutination. The red cells of three cases reported by Moss showed a variable and usually increased resistance to hypotonic salt solution, never a resistance less than that of normal corpuscles. All three cases gave a positive Wassermann reaction.

110. **Signs of Pulmonary Tuberculosis.**—The small pendulous heart, calcified cartilages, narrow interspaces and excessive sloping of the ribs, are held to be not only valueless, by the authors, but as absolutely misleading, if considered as positive signs in the radiographic diagnosis of pulmonary tuberculosis.

111. **Tuberculo-Protein Hypersensitiveness.**—Hypersensitiveness to tuberculo-protein, Krause believes, is most likely never handed down to the third generation. This conclusion is based on tests made on nine animals, the grandchildren of sensitized females through the female line. The fact that a number of animals were born sensitive over 100 days, and several 379 days, after their mothers' last injection Krause regards as direct evidence that the transmission may be one of anaphylactic antibody and not of the antigen. He says that the possibility of maternal inheritance is more or less irregular and inconstant. It depends largely on the degree of sensitiveness of the mother at the time of pregnancy. The degree of sensitiveness of the offspring as a rule varies directly with that of the mother. The mother's sensitiveness is heightened by repeated applications of antigen, and, conversely, tends to die out with time unless renewed by subsequent injections. The degree of sensitiveness of the offspring accordingly varies, depending on the time that has elapsed between the mother's last dose and the birth of the offspring. The degree of sensitiveness that an animal inherits tends to diminish as it increases in age and size. Animals of the same litter may vary greatly in the degree of sensitiveness which they inherit.

112. **Leukocyte Count in Normal Rabbits.**—The normal variation in the total leukocyte count taken at the same hour each day of rabbits kept as nearly as possible under constant conditions, Moss and Brown found to be very great, at times reaching nearly 100 per cent. They observed quite regularly a diurnal cycle in which they are inclined to ascribe the increase in the number of leukocytes to the influence of digestion. They observed that an increase in the total leukocyte count was participated in, as a rule, by both the polymorphonuclear

twenty-four hours and then gradually fades. The cases tested were divided as follows: Of twenty-seven cases of (1) cancer in various stages; (2) patients in whom cancer had just been removed; and (3) cases in which the diagnosis was not determined pathologically, a positive reaction was obtained in nine cases, a negative reaction in sixteen cases, doubtful in two cases. Of seventy-three non-malignant cases the reaction was positive in fifteen cases, negative in fifty-five cases and doubtful in three cases. Risley believes that the test is only suggestive and is rendered practically valueless as a diagnostic aid because of the fact that there are undoubtedly present in the blood of many patients other lysins of unknown nature which bring about hemolysis of varying degrees. This test, therefore, as the test done *in vitro*, fails to be of any practical value in the diagnosis of malignancy. It is highly significant, but will require further investigation or a more refined technic before becoming of value.

68. **Chemical and Microscopic Findings.**—Austin agrees with A. Schmidt that the atrophy of the intestinal glands does not cause pernicious anemia nor conversely does pernicious anemia cause any changes in the intestinal mucous membrane which are not produced by many other agencies.

74. **Prostatic Suggestions.**—That there is a period in prostatic disease which is being more definitely recognized than previously which rests on the condition of the bladder mucous membrane due to the disease, is the principal point made by Pedersen. He says that if the mucosa is in good condition and the prostate gland has begun to obstruct, the best time for operation is at hand. Delay until the mucosa is greatly injured will mean hazard and likelihood that the injury will be permanent and beyond repair. When the mucosa of the bladder has begun to suffer, it is often because the obstruction by the prostate gland and the cystitis have reached a degree which soon leads to serious results on the kidneys and ureters above. The mere removal of an enlarged and obstructing prostate gland may be mechanically possible and performed without death, but if a bladder is left behind so badly damaged from chronic cystitis as to render functional restoration impossible and as to leave the symptoms proceeding from the bladder virtually unchanged, then the operation has failed of its ideal success. If the prostate gland is merely enlarged, obstructs none or very little, and the bladder is in good condition, operation is not justifiable. If the bladder is changed from inflammation beyond recovery, and if the catheter may be successfully passed, in most cases irrigation is preferable and more conservative than operation.

89. **New Term in Skiascopy.**—The sign to which Claiborne refers and which is characteristic of spherical errors (the behavior of the shadow in spherical errors), he says, is to be seen only when the mirror is turned in a circle, or rotated on an anteroposterior axis. He uses the concave mirror, and employs skiascopy for the purpose of qualitative, approximately quantitative, estimates of refraction and the proving of the functional examination. When the mirror is rotated on the anteroposterior axis, either in spherical myopia or hypermetropia, the shadow moves in the circle, and ultimately always in the same direction with the movement of the mirror. It resembles the turning of a wheel on an axle, or a revolving circle. The shadow chases itself around the pupil. In hypermetropia, speaking from the standpoint of the concave mirror, as the circular movement commences, the shadow is observed to creep from the opposite side of the pupil and chase itself in a circle from left to right, when the mirror is moved from right to left; or, from right to left, when the mirror is moved from left to right. The movement in this case is against the movement of the mirror, and yet each shadow chases the other in the same direction. In the case of myopia, the shadow moves with the movement of the mirror, and starts from the quadrant in which the circular movement of the mirror starts and chases itself around the pupil as in hypermetropia. The movement in both cases, therefore, is purely circular, and the shadow appears to move always in the same direction, though in the two cases it starts from opposite directions. The degree of the error is indicated by signs which are well known to all those conversant with this method—a gray slow shadow indicating high error, a black rapid shadow low error.

96. **Cutting of Optic Nerve.**—This question is answered by Emerson in the affirmative. In a case of glaucoma he cut the optic nerve and the patient stated that he saw "lightning." There is no doubt in Emerson's mind that the cutting of the optic nerve elicited the sensation of light.

97. **Mydriatic Ozena.**—For a few years back Rhoads has noticed that some of his patients emanate a fetid nasal odor a short time after the first instillation of a mydriatic. Cases that had the slightest trace of ozena before the instillation of drops were not recorded. The odor diminishes with the effect of the drops, consequently four hours after the last drops have been put in many patients have very little if any odor, and when they come back for "sync myd." examination, or to have their glasses verified there is not the slightest trace of it. The odor comes and goes with the mydriatic.

108. **Stereoscopic Roentgenography of Chest.**—The object of this paper is to call attention to the principles and technic of stereoscopic *x*-ray examinations, and to describe the alterations in the normal chest shadows, which the authors believe to be characteristic of pulmonary tuberculosis. The shadows within the chest cavity are divided into three main groups: first, the "heavy central shadow," extending irregularly from the upper boundary of the chest cavity to the diaphragm; second, the "hilus shadow," radiating irregularly to a distance of four or five centimeters on either side of the fifth, sixth and seventh dorsal vertebræ; and third, the "linear markings" seen in the lung fields. The "heavy central shadow" is cast by the vertebræ and the mediastinal contents; the heart, aorta and other large vessels, trachea, esophagus, lymphatics and connective tissue. The hilus shadow is cast by the primary branches of the pulmonary vessels with their contained blood, the walls of the primary bronchi, and the lymphatic and fibrous tissue surrounding these structures. The shadows in the lung fields are subdivided into two groups; the heavy trunks and the fine linear markings. The heavy trunks are the shadows of the large branches distributed to separate lobes of the lung, the linear markings are the shadows cast by the smaller branches distributed to the various lobules of the separate lobes. In cases of pulmonary tuberculosis, changes are noted in the hilus shadow, the heavy trunks and especially in the linear markings. The hilus shadow shows usually an irregular increase in area and density with here and there small irregular shadows of very marked density. These bright areas of great density are due to the presence in the chest of calcified caseous or fibrous glands, while the increased area and density of the hilus shadow is due to a general increase in the fibrous and lymphatic tissue which accompanies a local or general mediastinitis. Such changes alone are regarded by the authors as of very slight diagnostic value as regards the presence of active tuberculosis, since other infections may produce the mediastinal changes and the calcified glands, although probably of tuberculous origin, indicate an old process more or less healed. In fact the presence of calcified glands, the other conditions being favorable, may be taken as a good prognostic sign. The heavy trunks extending toward the involved area usually appear broader, denser and less regular in outline than in the normal. Here again this change in the heavy trunks is not necessarily tuberculous in origin, so that too great importance must not be attached to this change alone. The fine linear markings appear broader, denser and less regular in outline, frequently their course is studded, sometimes almost to obliteration of the lines; they appear to cross and interweave, producing a delicate network of varying-sized mesh. The anatomic explanation of this altered shadow picture the authors are not at this time ready to discuss, but they firmly believe that the increase in the hilus shadow, the thickening of the trunks, together with the alterations in the linear markings, increase in density and breadth, studding, interweaving and extension to the periphery, constitute a shadow picture characteristic of early pulmonary tuberculosis. As the lesion progresses the alterations become more marked, the linear markings are more and more broken up and irregular, the studdings become larger and denser and the interweaving closer, until eventually the whole area appears as a more or less homogeneous shadow of increased density, due to the presence of gross areas of consolidation within the lung.

109. **Paroxysmal Hemoglobinuria.**—The serum of patients suffering from paroxysmal hemoglobinuria, Moss found, contains a complex hemolysin, of amboceptor-complement nature, which is capable of bringing about the solution of the patient's own corpuscles, corpuscles of other paroxysmal hemoglobinuric patients, and of all other individuals, as far as tested. Patients suffering from paroxysmal hemoglobinuria are not confined to one group, as determined by the iso-agglutination reaction, and their serum may contain normal isohemolysin in addition to the hemolysin characteristic of their disease. The auto-amboceptor may be absorbed from patient's serum, leaving the iso-amboceptor and conversely the iso-amboceptor may be absorbed, leaving the auto-amboceptor, thus enabling each to be tested separately on any given set of corpuscles. Only the amboceptor component of the hemolysin of paroxysmal hemoglobinuria is peculiar to the disease. The complement differs in no way, so far as tested, from that present in normal serum. The amboceptor peculiar to paroxysmal hemoglobinuria differs from other known hemolytic amboceptors in that it will unite with the red blood-corpuscles only at a low temperature in the presence of complement, and furthermore, in that it is capable of bringing about the solution of the patient's own cells (auto-hemolytic action) and those of other members of the group to which the patient belongs, as well as the cells of members of other groups. Hemolysis due to the autohemolysin of paroxysmal hemoglobinuria, unlike normal isohemolysis, may occur entirely independently of agglutination. The red cells of three cases reported by Moss showed a variable and usually increased resistance to hypotonic salt solution, never a resistance less than that of normal corpuscles. All three cases gave a positive Wassermann reaction.

110. **Signs of Pulmonary Tuberculosis.**—The small pendulous heart, calcified cartilages, narrow interspaces and excessive sloping of the ribs, are held to be not only valueless, by the authors, but as absolutely misleading, if considered as positive signs in the radiographic diagnosis of pulmonary tuberculosis.

111. **Tuberculo-Protein Hypersensitiveness.**—Hypersensitiveness to tuberculo-protein, Krause believes, is most likely never handed down to the third generation. This conclusion is based on tests made on nine animals, the grandchildren of sensitized females through the female line. The fact that a number of animals were born sensitive over 100 days, and several 379 days, after their mothers' last injection Krause regards as direct evidence that the transmission may be one of anaphylactic antibody and not of the antigen. He says that the possibility of maternal inheritance is more or less irregular and inconstant. It depends largely on the degree of sensitiveness of the mother at the time of pregnancy. The degree of sensitiveness of the offspring as a rule varies directly with that of the mother. The mother's sensitiveness is heightened by repeated applications of antigen, and, conversely, tends to die out with time unless renewed by subsequent injections. The degree of sensitiveness of the offspring accordingly varies, depending on the time that has elapsed between the mother's last dose and the birth of the offspring. The degree of sensitiveness that an animal inherits tends to diminish as it increases in age and size. Animals of the same litter may vary greatly in the degree of sensitiveness which they inherit.

112. **Leukocyte Count in Normal Rabbits.**—The normal variation in the total leukocyte count taken at the same hour each day of rabbits kept as nearly as possible under constant conditions, Moss and Brown found to be very great, at times reaching nearly 100 per cent. They observed quite regularly a diurnal cycle in which they are inclined to ascribe the increase in the number of leukocytes to the influence of digestion. They observed that an increase in the total leukocyte count was participated in, as a rule, by both the polymorphonuclear

and small mononuclear leukocytes, but usually by the latter to a greater extent than by the former. The relative values (percentage values) of the polymorphonuclear and small mononuclear leukocytes bear a reciprocal relation to each other; that is, an increase in the percentage of one is accompanied by a decrease in the percentage of the other. They were unable to observe that the intravenous injection of normal horse serum in doses varying from 0.1 c.c. to 5 c.c. or the intradermal injection of 0.01 c.c. normal horse serum in either sensitized or non-sensitized rabbits had any definite or constant influence on the total or differential leukocyte counts, three hours or longer after injection.

113. **Antiformin in Examination of Sputum for Tubercle Bacillus.**—Boardman recommends the use of sodium hypochlorite solution (antiformin) in the examination of sputum for tubercle bacilli not only in hospitals and dispensaries, but in the laboratory of every private physician. He holds that the general adoption of this method, combined with repeated examinations, will do much towards reducing the percentage of cases clinically diagnosed as definite pulmonary tuberculosis, in which, however, an absolute diagnosis cannot be made. Of far greater value than the finding of tubercle bacilli in the sputum of cases clinically diagnosed as definite pulmonary tuberculosis, is the possibility which this method offers of demonstrating bacilli in the cases still classed as only probable or doubtful, thereby enabling us to enforce a vigorous and systematic treatment at a time when such treatment is of most avail.

114. **Serotherapy of Hemorrhagic Diseases.**—The authors point out that the use of serum injections, the injections of defibrinated blood, and direct transfusion seem to have yielded better results in the treatment of hemorrhage than any other measures. As to the choice between these three procedures, doubtless direct transfusion would be the ideal method were it not for the technical difficulties.

115. **Much-Holzmann Reaction.**—The authors concur in the prevalent conclusion that the Much-Holzmann reaction has no diagnostic significance.

120. **Cutaneous Lesions and Leukemias.**—In the review of about sixty cases occurring in the literature Hazen says it can be seen that they can be divided into (1) acute lymphatic leukemia, (2) chronic lymphatic leukemia, (3) splenomyelogenous leukemia, (4) chloroma, (5) multiple myeloma, (6) lymphodermia perniciosa, to which grouping Dr. Strobel's case belongs, and (7) mycosis fungoides. In relation to the last it is interesting to note that Pardee and Zeit have recently reported a case of mycosis fungoides which later turned to a lymphatic leukemia. The lesions consist of pigmentation, edema, vesicles, papules, nodules, tumors, especially of the face, urticaria, diffuse erythrodermia, macules and pruritus. Histologically, the lesions are probably infiltrations of cells escaped from the blood, and not proliferation of preexisting lymphoid tissue. Treatment should be directed towards the general condition and towards the relief of itching and the prevention of cutaneous infection. The Roentgen ray would probably do more to help the skin lesions than any other therapeutic agent.

124. **Influence of Pregnancy on Diseases of the Eye.**—This paper is essentially a plea for systematic and careful examination of the eyes of pregnant women by obstetricians, with the view of safeguarding the vision and even sometimes the lives of these women.

5. **Surgical Interference in Cancer.**—Experimental study has convinced Paine and Nicholson that the behavior, after operation, of two tumors in contiguity lends support to the view that the increased virulence of the recurrence is mainly due to increased blood-supply. It is occasionally stated that this increase is due to the heightened general metabolism of the body called forth by the neoplasm, which, on removal of its main mass, is made use of by such portions as have remained undisturbed. That this is not so was demonstrated by the behavior of two tumors on opposite sides of the body, whose blood-supply is quite independent. In such a case, of which the authors had six, removal of one tumor, even if large, produced no difference in the rate of growth of the other, though this be small. Furthermore, a tumor of a slowly growing series often recurs rapidly after operation; such rapid recurrence may even take place during a negative phase; and the transplantations from an operated tumor (which has recurred rapidly) into healthy mice do not show an increased rate of growth in any way proportionate to that of the recurrence. In eleven out of forty-eight operations—that is, in 23 per cent.—the recurrence was both early and virulent, its rate of growth being in some instances two or three times as rapid as that of the primary tumor or as of the tumors of the remaining mice of the series. This increase in the virulence, the authors claim, is mainly due to the remaining fragments having a very rich blood-supply and not to relief of tension or pressure.

6. **Influence of Calcareous Drinking-Water.**—Lewis claims that there is no evidence that hard water has any bad effect; on the contrary, all the evidence is the other way.

9. **Overdistention of Lung and Pneumothorax.**—In pneumothorax, Walsham says, the shadow of the collapsed lung can always be seen, while in the overdistended lung it is never so seen.

11. **Stomach Dilatation.**—Six new cases are cited by Box and Wallace to support in the main their former contention that the pressure exerted on the duodenum by the dilated stomach is an important factor in the production of obstructive symptoms. Beyond reiterating the importance of combining lavage with the prone position nothing new is offered as regards treatment.

12. **General Subcutaneous Non-Renal Edema as Familial Affection.**—Six children born to healthy parents developed a subcutaneous edema at ages varying from 1 to 15 weeks. In one case it was slight and confined to the face, and the child recovered; in the other five, death ensued after a period of from one to sixteen weeks. In three, at least, of the cases no albumin was present in the urine. In the two cases examined post mortem no evidence of nephritis was found. All the patients suffered from a more or less marked diarrhea shown by green liquid motions before, in some instances only a few hours before, the occurrence of the dropsy. The children thus suffered from an intestinal catarrh and the dropsy was a related phenomenon. Edgeworth suggests that the edema may have been due to a damage to the walls of the capillary blood-vessels by poisons absorbed from the alimentary canal without the occurrence of any change in the excretory capacity of the kidneys. Thus in one of the cases it was found that the administration of calcium chlorid diminished the edema. The occurrence of intestinal dropsy in six successive children suggests to Edgeworth the possibility of an inborn defect in the walls of capillary blood-vessels whereby they may be more suceptible to poisons circulating in the blood than are the capillaries of normal individuals.

16. **Infarct of Transverse Colon.**—A woman, aged 49, had been troubled with hemorrhoids for some time, but was otherwise well, till she woke in the night with severe sense of pain in the epigastrium and flatulence. She blamed the cocoa she had had for supper. The next day diarrhea began and the pain in the abdomen increased. On the second day the diarrhea continued and there was nausea. Blood in the stools was first noticed in the afternoon. During the following night she had two actions of the bowels; both were practically pure blood, bright in color, and only very little fecal matter (perhaps ½ ounce in weight). Some clots were present of the size of half a hazel-nut—about 5 ounces of blood in each stool. This condition lasted for several days with vomiting, abdominal rigidity, no distention, pain below the navel and across the abdomen. The pulse and temperature were normal. A distinct thickening could be made out between the navel and the ensiform cartilage; it was tender and moved slightly on respiration. At the operation the transverse colon for the greater part of its extent was found to be of a dark purple color; the walls were greatly thickened. It did not look gangrenous. The ascending colon was anastomosed to the lower part of the descending colon. The patient did well for the first twelve hours. Then she had tetanic spasms, which continued at intervals of a few minutes for nearly twelve hours when she died. There were minute hemorrhages in the walls of the colon which were microscopically shown to be in a condition of infarct. The branches of the colica media were empty; no emboli were found; there was no peritonitis, but there were hemorrhages in the transverse mesocolon. There was a small amount of blood-stained fluid in the peritoneal cavity. Microscopic examination of the mesenteric arteries did not show any sclerotic changes. There was an old mitral lesion, with some narrowing of the orifice, and a few vegetations on the edges of the valve.

23 *Early Cardiac Paralysis and Hemiplegia in Diphtheria. C. Burrows

23. **Cardiac Paralysis and Hemiplegia in Diphtheria.**—On the eighth day of an attack of severe faucial and nasal diphtheria the earliest suggestion of the coming cardiac trouble presented itself; the first sound of the heart, which up to this time had been quite clear, was noted to be "distant" in quality. For this reason the child was given epinephrin by mouth—m x of a 1 in 1,000 solution—every four hours. For the next three days the first sound of the heart retained the same distant quality, the pulse keeping quite regular. On the twelfth day vomiting occurred. The face was pallid, and the pulse was small but regular. The quality of the heart-sounds remained as before, but the rhythm of the beats was beginning to be disturbed, the short space being shortened, and it was evident that cardiac paralysis had set in. There was still albumin in the urine. All nourishment by mouth was withheld and the patient given rectal feeding, consisting of peptonized milk every four hours, to each of which m xx of the epinephrin mixture was added. Nothing was given by mouth. During the next twenty-four hours the child vomited twice. On the thirteenth day the cantering rhythm or the *bruit de galop* was observed. The pulse was rapid but not irregular. For the following four days the vomiting and retching were very frequent, and continued for eight days altogether, but with lessening frequency. On the fifteenth day the cantering rhythm was still present, the apex-beat being within the nipple line at this time. The sounds were fairly strong. On the seventeenth day there was frequent vomiting, and the heart was much dilated, the apex-beat being ½ inch outside the nipple line. The pulse was very rapid, as were also the heart-sounds, but the cantering rhythm was not heard.

At this time tincture of digitalis, m v, was added to each rectal feeding. Before the administration of the digitalis in the rectal feedings the pulse-rate was 124. The next day the pulse-rate was 132, and the day following the pulse remained small and very irregular. On the third day of the administration of digitalis, the pulse-rate fell to 72. The tincture of digitalis was then only given in every second rectal feed. The following day it was given only in every third feed, and the pulse-rate keeping at 72 to 80 the digitalis was omitted altogether three days afterwards. The pulse-rate kept the same for a week when it slightly increased in rapidity (88-100) and remained much the same until the child's discharge from the hospital. The patient thus appeared to benefit from administration of the digitalis. The nasal twang of the voice continued until the fifty-ninth day of the disease. On the forty-second day the knee-jerks were found to be absent. On the forty-third day paralysis of the left upper limb occurred, the child lifting and moving this arm about with the right arm, which was quite normal. A few days after the paralysis of the arm was noted the left leg was also found to be paralyzed. There was no aphasia. No knee-jerks were present on either side, although the right leg was quite readily moved by the patient. On the fifty-sixth day some difficulty in swallowing presented itself with some dribbling of saliva from the mouth. The diaphragm was not affected. Left internal paralytic strabismus was still present. Thirty days after the onset of the hemiplegia, the left arm and leg had both almost recovered their normal state, the only paralyzed muscles being the extensors of the left thumb and the peronei muscles of the left leg. This condition remained unaltered up to the time the child was discharged from the hospital. Six months afterward the extensors of the left thumb were still weak, and the flexors overacting drew the thumb towards the palm. The child consequently picked up objects with this hand awkwardly. The hand-grip was weak, but seemed to be a trifle stronger than it was four months previously. The muscles of the left arm and forearm seemed a little stiff, but all the movements were free. She could walk better than when she left the hospital, there being almost imperceptible dragging of the left foot; the peronei muscles were, however, still weak, so that the foot could not be thoroughly everted. No knee-jerks were obtainable on either side. The child's health was good and her mental condition excellent. The right arm and leg were quite normal; the heart appeared to be quite sound.

27 Suppurative Antrum, Acute and Chronic. S. Hastings.
28 *Fourteen Consecutive Successful Laparotomies for Acute Intussusception in Infants. E. W. Roughton.

28. **Laparotomies for Acute Intussusception in Infants.**—There was no mortality in this series of fourteen cases reported by Roughton. The patients were all operated on with the least possible delay and without any previous treatment by inflation or injection. In all the cases the invagination occurred during the first year of life. The oldest was 12 months and the youngest 4 months. Ten of the children were males and four females. One case was enteric, the lesion being a few inches above the ileocecal valve; one was ileocecal ileocolic, i. e., after reducing the common ileocecal invagination a few inches of ileum which had prolapsed through the valve had to be drawn out. The other twelve cases were of the ordinary ileocecal variety, and in nearly all of them it was noticed that the caput ceci was the last part to unfold; in other words, the apex of the intussusception must have been [illegible]ied by the invaginated caput ceci, and not by the ileo-[illegible] valve itself as is often stated in text-books. Roughton [illegible] that in nearly every case of intussusception the trouble [illegible] from what might be called want of tact on the part [illegible]ne ileocecal valve. If the child's bowels are disordered, [illegible]duly active peristalsis hustles the contents of the small [illegible]tine along so fast that it tries to pass the valve before it has been sufficiently digested. In four of Roughton's cases there was a definite history of diarrhea, vomiting or constipation preceding the onset of the intussusception, and he believes that the more often one inquires for a history of previous gastro-intestinal disturbances the more often will it be found that intussusception occurs in children whose bowels are already disordered by flatulence or diarrhea. In one case no tumor was palpable even under the anesthetic, the reason being that the tumor was very small and soft; it was of the enteric variety. The absence of a lump, therefore, must not deter the surgeon from opening the abdomen. Roughton is strongly of the opinion that when efficient surgery is available, distention of the colon with wind or water is a method of treatment which should no longer be employed. If he were so situated that an abdominal section was impossible or unjustifiable, he would employ injection, but in no other circumstances would he do so. Roughton's contention is that if the cases are diagnosed early and treated by laparotomy without wasting precious time over injection or inflation, recovery would almost always follow.

35 Water-Supply and Enteric Fever. G. C. Jones.
36 Harrogate: Its Waters and Its Baths. J. Rutherford.

33. **Asthma in Children.**—For preventing the recurrent attacks of asthma there is no drug, in Moon's experience, so effective as arsenic. Beginning with liquor arsenicalis, m. ii, t.d.s., *it may gradually be increased*; but there is *no object* in pushing it to large doses. Moon has found it *most* satisfactory to give the arsenic alone, and if the attacks are recurring rather frequently to prescribe also at bed*time*:

℞	Gm. or c.c.	
Potassii iodidi	2	gr. iii
Vini ipecacuanhæ	33	m. v
Syrupi tolutani	66	m. xx
Aquam .... ad 30		ad ℥ j

M. S.: *To be taken at bedtime.*

Moon says other remedies which *may* at times prove useful are lobelia in the form of the tincture, 10 minims every half hour, till the paroxysm is allayed, or the *physiologic* effects—nausea and a feeling of *faintness*—disappear. Similarly, belladonna may be given at frequent intervals till the paroxysm ceases or the *physiologic effects* are present. The liquid extract of grindelia, m. 10-15, every three hours, flavored with syrup of orange peel to conceal its unpleasant taste, will often cut short an attack of asthma. Moon cautions that we must always remember that most of the patent powders and medicines which claim to be cures for asthma *are in the nature* of depressants, and are therefore quite unsuited *in most* cases, for children. Apart from this, *they* only *attempt to deal* with the paroxysm, and *therefore no effort* is made to brace up and harden the nervous *system*, which in Moon's opinion, is the most important *thing to do* if we wish to treat asthma scientifically.

45 Case of Tetanus Treated by Subdural Injection of Antitoxin. R. J. Millard.

37. **Intestinal *Flora*.**—Reissmann states emphatically that the lactic *acid treatment* of intestinal putrefaction is not a panacea for all ills, but its value in cases of excessive intestinal putrefaction has been *proved*. Neither is its efficacy to be *called* in question, because a large number of so-called preparations of the lactic acid bacillus are marketed which on examination have been found not to contain the *living* bacillus. Also we should not attribute to the *action* of the lactic acid germ results which may have been produced by special dieting.

43. **Congenital Heart-Block.**—The *patient*, 3 years *old*, though small for her age, was fairly well nourished. She could stand, but not walk. She had a purplish-red color in her cheeks. The abdomen was full, and the liver uniformly enlarged, but not tender. The pulse was perfectly regular; the rate as counted for the full minute by the stethoscope was 50, the net count being 49. No pulsation visible *in* the veins in the neck; precordial *pulsation not unduly* noticeable. Percussion showed *increased* dulness upwards. The heart sounds were *normal*. The respiration rate was 50; but the heart rate and *respiration* rate though almost always coinciding, occasionally deviated a little. Now and then there would be a deep sighing inspiration, followed by a longer *pause than usual*, but during this pause the heart would continue to beat as before. Growth took place very slowly, her general condition showing a gradual improvement. She never had any epileptiform seizures. The pulse rate varied between 47 and 60, but was generally about 50 or a little more. About two years after Gill first saw the girl, he *made* a pulse tracing. There was no murmur or thrill. The heart was evidently hypertrophied as shown by the protrusion of the chest-walls. He could not be sure of any pulsation in the jugulars, and could get no record of any with the polygraph, but the neck was very short. Five months later she had a slight attack of tonsillitis, the temperature being 101, the pulse rate was 64, heart beat and respiration corresponding as before, except when she coughed; the interruption in the breathing caused thereby did not interfere with the heart-beat, which would continue at the same regular rate as usual. In the morning she seemed to be better, and was running about. Death took place quite suddenly in the afternoon. No post-mortem was allowed.

54 *Tardy Gastric Pains from Spasm of the Pylorus in Winter with Chronic Gastric Ulcer. H. Boschi.

52. **Cancer of the Umbilicus Secondary to Cancer of the Stomach.**—The patient in the case reported was a woman of 34 who applied for relief for pains in the stomach first noted three months before in the midst of apparently perfect health. The pain appeared with symptoms of indigestion and was transiently relieved by vomiting, and she was losing constantly in weight. There was no pain before breakfast but it came on an hour and a half to three hours after meals and woke her at night. The umbilicus was found slightly protruding with a hard, stem-like tumor extending backward to a primary cancer at the pylorus. In the sixty-three cases of cancer of the umbilicus on record, forty-four of the patients were women. Oettinger and Marie emphasize the importance of examining the umbilicus to detect cancer in its incipient phase; there may be merely partial retraction of the umbilicus, the folds a little protruding, a minute lump palpable, not knobby and projecting, but hard, asymmetrical, drawing the umbilicus inward or there may be a small, hard border below the umbilicus. In a few cases the cancer early developed a fistula. Primary cancer requires, of course, prompt removal, but a secondary cancer at the umbilicus generally contraindicates operative treatment unless hemorrhages or pain compel it. If a palliative operation is done, such as the gastro-enterostomy in the case reported, it is advisable to resect the umbilical tumor at the same time for obvious reasons.

54. **Tardy Gastric Pain with Chronic Ulceration.**—Boschi has encountered five cases of chronic gastric ulcer in which during the winter there were recurring attacks of painful spasm of the pylorus. Kouchew has reported four similar cases of trouble only in the winter and Murri has called attention to the gastric disturbances during the winter which sometimes accompany chlorosis. The explanation seems to be that the action of the cold on the nerve terminals and vasomotor nerves causes contraction of the superficial vessels, expelling the blood and forcing it inward to the viscera, causing congestion in the abdominal vessels. The weakest of the viscera—the stomach with a chronic tendency to ulcer in his cases—feels the effect of the congestion most severely. The congestion in the stomach causes the old ulcer to flare up anew, with irritation of the local nerves and reflex pylorospasm. The kidneys are liable to suffer by the same mechanism in winter if a predisposition exists.

55. **Massage for Parenchymatous Keratitis.**—Grandclément has been advocating for nearly thirty years vigorous massage of the eye-ball applied for fifteen minutes ten or fifteen times a day, lubricating with a little salve so the eyelids can slide easier over the eye-ball. Done in this way he has been able to cure parenchymatous keratitis in seventy days unless there were pronounced Hutchinson teeth, in which cases the course required from ninety to a hundred days to accomplish the same results. If the leukocytes that have invaded the cornea in such quantities are left in peace, there is more or less blindness for months or years. But if with vigorous, constantly repeated massage the leukocytes are kept stirred up and mobilized, they are easily swept along by the circulating blood and the massage aids in developing the blood-vessels that flush out the leukocytes. During the entire course of treatment he keeps the pupil dilated with atropin to prevent any complications on the part of the iris, especially posterior synechia. The course may be completed or hastened by a few conjunctival injections of a 1 or 2 per cent. salt solution. He has never witnessed any benefit on the keratitis from iodid or mercury.

67* Hour-Glass Stomach with and without Gastric Ulcer. (Ueber Ulcus penetrans ventriculi und Sanduhrmagen.) H. Strauss and S. Brandenstein.

67. **Hour-Glass Stomach With and Without Gastric Ulcer.**—Strauss and Brandenstein report three interesting cases to show the important information in regard to hour-glass stomach and other forms of spastic contraction in the digestive tract to be learned from examination with the Roentgen rays. In the first case a penetrating ulcer had entailed a slight perigastritis which had resulted in adhesions, drawing up the stomach and forming a loose fold projecting into the interior and producing the effect of an hour-glass stomach, although not actually obstructing the passage. The condition was suspected before the operation on account of the short distance to the right of the median line. They urge others to investigate this question as to the displacement to the left of a stomach with motor insufficiency in connection with symptoms of an ulcer as a sign of deforming perigastritis. In the second case the penetrating ulcer was found associated with a carcinoma opposite the protruding fold in the stomach. This case teaches that the Haudek symptom-complex—which was marked in this case—does not exclude cancer. In the third case the constriction in the stomach wall was occupied by a roll of muscle, the size of a pencil, which passed through the entire length of the groove, encircling the stomach, and there were no traces of carcinoma, ulcer or erosion; the trouble seemed to be merely a localized hypertrophy of the muscle tissue. There was no motor disturbance in this case, but the gastric secretion was deficient. The patient was a woman of 48 who had had gastric disturbances two years before and for nearly a year there had been spasms of pain in the stomach region, especially after eating, but sometimes fasting, with vomiting after meals and gradual loss of nearly 90 pounds in weight. The constricting cord of muscle could be palpated and it was resected with a strip of stomach wall. These cases suggest further that the discovery of the hour-glass stomach is just the beginning of the diagnosis.

73 Improved Technic for Making Iodized Catgut. (Vereinfachung der Herstellung des trockenen Jodkatguts.) K. F. Herhold.

70. **Diagnostic Importance of Pepsin in the Urine with Gastric Cancer.**—Scholz reported recently that no pepsin was found in the stomach content or urine in his cases of uncomplicated gastric achylia while with gastric cancer and achylia

there was no pepsin in the stomach content but more or less peptic ferment was found in the urine. His statements, based on sixty-six cases, have been challenged by certain others but he reiterates here that renewed research, which he describes, has confirmed the accuracy of his first statements. Consequently he reaffirms that in dubious cases of gastric cancer strong presumptive corroborative evidence is afforded by the discovery of pepsin in the urine when the gastric juice after a test breakfast, is free from pepsin and this finding is confirmed also after a bouillon breakfast.

91 Two Years of the Movement for Infant Welfare. (Zwei Jahre offene Säuglingsfürsorge in Nürnberg.) E. T. J. Zeltner.

83. **Intravenous Ether Anesthesia.**—Hagemann reviews the experiences at the Greifswald surgical clinic, in charge of König, with intravenous injection of ether in a total of eleven cases. The patients submitted to this technic were those requiring operations on the mouth or face or in extreme cachexia. By mixing the ether with cold water and gradually warming over the water bath to 38 C. (100.4 F.) and keeping the fluid at this temperature, all excess of ether evaporates and a 4.68 per cent. solution results. From 1,050 to 3,925 c.c. of the solution were thus infused; there was no sign of thrombosis or embolism and he thinks that the technic is so free from danger that it is justified for the operations in which it offers superior advantages, especially those on the face. The infusion of such large amounts of fluid is also of advantage in much debilitated patients; the pulse was never weaker but often stronger after the anesthesia and there was no thirst.

84. **Trypsin in Treament of Surgical Tuberculosis.**—Brandes reports from Kiel considerable experience in this line. The results were not sufficiently promising to render the clinic disloyal to the old tried and tested 10 per cent. iodoform-glycerin treatment. This really is an indirect ferment therapy as it attracts the leukocytes to the spot.

86. **Subperiosteal Resection of Shaft for Ostitis of the Fibula.**—Sulzer has been comparing the ultimate outcome in a number of cases of acute purulent ostitis of the fibula treated by various methods. Seven cases are reported in detail as typical of the various experiences. In the cases in which treatment by subperiosteal resection of the shaft, the lesion healed promptly and permanently, while with the more conservative measures the affection dragged on tediously or recurred again and again. This resection of the shaft does not interfere with normal growth or functioning, while the prompt removal of the focus removes all danger of sepsis.

96 Fatal Lysol Poisoning. (Lysolvergiftung mit Aspiration in die Luftwege und konsekutivem Empyem. Karbolverätzung der Luftwege mit tödlichem Ausgang.) A. Cahn.

92. **Organotherapy.**—Hirsch reviews the history of this branch of medicine from the days of Hippocrates and Celsius to the latest catalogues of the manufacturing chemists. While doing full justice to the achievements in this line, he thinks that in some respects now organ preparations are being carried to extremes, suggesting the absurdities of medieval apothecaries. He concludes with the remark that an effectual remedy against quackery is to be found in regulation of advertising, saying that the advertising of untested or nonsensical remedies and methods of treatment should be prohibited.

93. **Lime Salts in Treatment of Pregnancy Tetany.**—Meyer's patient was a small woman with signs of old rachitis who had had severe tetany during each of her three pregnancies; in the last it persisted a week after delivery. Meyer ordered a milk diet, abstention from salt, and a tablespoonful three times a day of a 4 per cent. solution of calcium chlorid, $CaCl_2$, with vegetables and fruit rich in the lime salts. Improvement was evident at once and in three days the woman was transformed. Recurrence of trouble after return to ordinary diet was again cured by resumption of the lime treatment. In a fourth pregnancy the same measures had to be resumed again and the effect was equally successful. All the woman's children showed signs of severe rachitis. Meyer gave the calcium merely in the hope of reducing the excitability of the nervous system and the results surpassed all his anticipations, as also in another case of tetany in the course of a nephritis. Curschmann has also reported the successful treatment of tetany in two cases with calcium lactate. Meyer adds that the harmlessness of this method of treating tetany justifies a trial of it in all cases of pregnancy tetany regardless of whether the parathyroid bodies are responsible for the trouble or not.

95. **The Wassermann Reaction as Guide to Treatment in Syphilis.**—Citron regards the Wassermann test as supremely important for determining the necessity for treatment, permitting individualization in each case and thus filling a long felt want. The test must be made with the original technic and should be repeated at intervals. Every return of a positive reaction should be regarded as a sign of active syphilis. He has made a point of testing the wives and children of syphilitics free from symptoms except a positive reaction, and he has found that they give a positive reaction in a surprisingly large proportion of the apparently healthy. This asymptomatic syphilis in many cases runs into an aortic affection, aneurysm or aortic insufficiency, tabes or paralysis. He comments on the remarkably large proportion of patients whose primary manifestation escapes their attention, his

experience confirming Fournier's that fully 50 per cent. of the tertiary syphilitic have no knowledge of any primary sore. The aim of treatment should be to transform a positive into a negative Wassermann reaction; the later specific treatment is commenced, the harder it is to accomplish this. The Wassermann reaction permits an estimate of the therapeutic effect of drugs, and salvarsan, while putting an end to other manifestations of syphilis, does not always insure a negative reaction. Mercury should still be the main reliance, possibly associated with salvarsan.

98 Splitting of Glucosids by the Brain. (Glykosidspaltung durch Gehirn.) L. Hess.
99 Experimental Tricuspid Insufficiency. S. Bondi and A. Müller.
100 *Salvarsan in Syphilis. V. Mucha. Commenced in No. 27.

97. **Serodiagnosis of Cancer.**—The extensive research here reported emphasizes the biologic interest of the newer serologic methods of diagnosis but does not indicate that they have much practical importance. The meiostagmin reaction, however, proved misleading in only two out of the twenty-six parallel tests. The Freund-Kaminer reaction, that is, the absence of the property of destroying cancer cells which is always observed with normal serum, is not peculiar to cancer cases, and the same may be said of the test by activation of cobra venom.

100. **By-Effects from Salvarsan in Syphilis.**—Mucha reports from the clinic for skin and venereal diseases at Vienna, in charge of Finger, forty-four cases of neurorecurrences in 500 syphilitics given salvarsan treatment. He describes them in detail, commenting that the disturbances involving the auditory nerve since salvarsan has been introduced far outnumber all the cases that have been recorded in international literature during the last twenty years. The fact that continuing the treatment sometimes cures the auditory disturbance sustains the assumption that the salvarsan injures the nerve in question, thus inducing a point of lesser resistance where the syphilis virus makes its influence felt more intensely. When the auditory disturbances subside spontaneously or persist rebellious to renewed treatment of the syphilis, the assumption seems plausible that the trouble was predominantly the result of the toxic action of the arsenic, and that after elimination of the drug the changes were so slight that complete restitution followed or so severe that this was no longer possible. An argument in favor of this view is the benefit obtained in two cases by sweats and injection of pilocarpin to promote elimination of the arsenic, without further specific treatment. There is still a further possibility, namely, that the salvarsan may have sensitized the syphilitic virus. In his experience there were eighteen cases of neurorecurrences in the ear in which the interval since infection was only six to twelve months. The neurorecurrences were observed with both subcutaneous, intramuscular and intravenous injection of the salvarsan. In conclusion Mucha reiterates that these so-called neurorecurrences are serious matters for the patient and frequently entail permanent injury, and the patients seldom care for further medication. Mucha's material includes besides the eighteen ear cases, six with general toxic phenomena, digestive disturbances, intense headache and dizziness, six with disturbances in other cerebral nerves, four with epileptiform attacks, two with cerebrospinal phenomena, five with optic neuritis, one with optic neuritis plus cerebral hemorrhage leaving motor and mental disturbance, one case of fatal meningo-encephalitis, three cases of nonsyphilitic meningitis seemingly aggravated by the salvarsan, and a case of nephritis for which he thinks the salvarsan was evidently responsible, as distinct traces of arsenic were perceptible in the urine nine months after the intragluteal injection of salvarsan and the nephritis showed great improvement under sweating procedures. Twenty-four pages are devoted to the details of the forty-eight cases in which striking symptoms followed the salvarsan treatment out of the total 500 cases. Finger's previous comment on his experiences was summarized in these columns June 10, page 1765.

101 *Tincture of Iodin in Treatment of Surgical Tuberculosis. F. Franke
102 *Double Opening in Gastro-Enterostomy. (Die neue Ruggi'sche Methode der doppelten Verbindungsöffnung zwischen Jejunum und Magen bei der Gastroenterostomie.) G. Rocchi and U. Stoppato
103 *Early Diagnosis of Suppuration in and Around the Kidney. (Zur Frühdiagnose der paranephritischen Eiterung und des Nierenabszesses.) E. W. Baum.

101 **Tincture of Iodin in Surgical Tuberculosis.**—Franke states that he has been using tincture of iodin systematically for the last ten years in sterilization of the field of operation for tuberculosis of the soft parts. He fills up the cavity with the concentrated tincture and then removes the excess with a syringe after a minute or two, or if the cavity is small merely tampons with gauze which sucks up the excess. He has never seen any untoward by-effects, except in one case in which a small bone sequester interfered with healing, but as he had used other disinfectants in this case the iodin need not be incriminated. Since adopting this technic he has scarcely ever had to amputate on account of surgical tuberculosis, even in the elderly, and the success of the measure is instructively shown in the case of a woman of 43 finally cured after a series of operations including resection of the right knee and ankle, curetting from the ankle to the hip for ascending tuberculosis of the soft parts of the outside of the leg, with resection of nine ribs and of the lower half of the sternum.

102 **Double Gastro-Enterostomy Opening.**—Rocchi and Stoppato give an illustration of the two openings on the same plane, or nearly at right angles, which Ruggi prefers for gastro-enterostomy, in prevention of the vicious circle. The space between is at least 2 cm.

103 **Early Diagnosis of Suppuration in and Around the Kidney.**—Baum states that bacteria are found in the urine in case of metastatic suppuration in and around the kidney much more regularly than is generally recognized. He obtained positive findings in all but one of seven cases of the kind, while the urine was constantly sterile when the suppuration was retroperitoneal. Staphylococci are generally responsible for the suppuration and their toxins injure the epithelium in the canaliculi, rendering the walls permeable for the germs even when there are no cellular elements in the urine.

107. **Morbid Taste in the Mouth on Arteriosclerotic Basis.**—Müller's patient was a man of 52 who had had an intensely sweet taste constantly in the mouth for three weeks. Signs of pronounced arteriosclerosis were evident, but nothing was found to explain the taste anomaly except the arteriosclerosis. The nervous system seemed normal and no benefit was derived from bromids. Theobromin sodium salicylate (diuretin) was then prescribed and the effect was prompt and complete, the taste becoming normal the same day. On suspension of the drug the disturbance returned, but was again cured in the same way and the patient now takes this drug continuously and has been free from the trouble for a year. Similar benefit was realized in another case in which the patient complained of attacks of pain in the tongue, for which no cause except arteriosclerosis could be discovered.

96 Fatal Lysol Poisoni[illegible] .it Aspiration in die Luftwege und [illegible] Karbolverätzung der Luftwege mi[illegible] A. Cahn.

92. **Organotherapy.**—Hirsch reviews the history of this branch of medicine from the days of Hippocrates and Celsius to the latest catalogues of the manufacturing chemists. While doing full justice to the achievements in this line, he thinks that in some respects now organ preparations are being carried to extremes, suggesting the absurdities of medieval apothecaries. He concludes with the remark that an effectual remedy against quackery is to be found in regulation of advertising, saying that the advertising of untested or nonsensical remedies and methods of treatment should be prohibited.

93. **Lime Salts in Treatment of Pregnancy Tetany.**—Meyer's patient was a small woman with signs of old rachitis who had had severe tetany during each of her three pregnancies; in the last it persisted a week after delivery. Meyer ordered a milk diet, abstention from salt, and a tablespoonful three times a day of a 4 per cent. solution of calcium chlorid, $CaCl_2$, with vegetables and fruit rich in the lime salts. Improvement was evident at once and in three days the woman was transformed. Recurrence of trouble after return to ordinary diet was again cured by resumption of the lime treatment. In a fourth pregnancy the same measures had to be resumed again and the effect was equally successful. All the woman's children showed signs of severe rachitis. Meyer gave the calcium merely in the hope of reducing the excitability of the nervous system and the results surpassed all his anticipations, as also in another case of tetany in the course of a nephritis. Curschmann has also reported the successful treatment of tetany in two cases with calcium lactate. Meyer adds that the harmlessness of this method of treating tetany justifies a trial of it in all cases of pregnancy tetany regardless of whether the parathyroid bodies are responsible for the trouble or not.

95. **The Wassermann Reaction as Guide to Treatment in Syphilis.**—Citron regards the Wassermann test as supremely important for determining the necessity for treatment, permitting individualization in each case and thus filling a long felt want. The test must be made with the original technic and should be repeated at intervals. Every return of a positive reaction should be regarded as a sign of active syphilis. He has made a point of testing the wives and children of syphilitics free from symptoms except a positive reaction, and he has found that they give a positive reaction in a surprisingly large proportion of the apparently healthy. This asymptomatic syphilis in many cases runs into an aortic affection, aneurysm or aortic insufficiency, tabes or paralysis. He comments on the remarkably large proportion of patients whose primary manifestation escapes their attention, his

experience confirming Fournier's that fully 50 per cent. of the tertiary syphilitic have no knowledge of any primary sore. The aim of treatment should be to transform a positive into a negative Wassermann reaction; the later specific treatment is commenced, the harder it is to accomplish this. The Wassermann reaction permits an estimate of the therapeutic effect of drugs, and salvarsan, while putting an end to other manifestations of syphilis, does not always insure a negative reaction. Mercury should still be the main reliance, possibly associated with salvarsan.

00 *Salvarsan in Syphilis. V. Mucha. Commenced in No. 27.

97. **Serodiagnosis of Cancer.**—The extensive research here reported emphasizes the biologic interest of the newer serologic methods of diagnosis but does not indicate that they have much practical importance. The meiostagmin reaction, however, proved misleading in only two out of the twenty-six parallel tests. The Freund-Kaminer reaction, that is, the absence of the property of destroying cancer cells which is always observed with normal serum, is not peculiar to cancer cases, and the same may be said of the test by activation of cobra venom.

100. **By-Effects from Salvarsan in Syphilis.**—Mucha reports from the clinic for skin and venereal diseases at Vienna, in charge of Finger, forty-four cases of neurorecurrences in 500 syphilitics given salvarsan treatment. He describes them in detail, commenting that the disturbances involving the auditory nerve since salvarsan has been introduced far outnumber all the cases that have been recorded in international literature during the last twenty years. The fact that continuing the treatment sometimes cures the auditory disturbance sustains the assumption that the salvarsan injures the nerve in question, thus inducing a point of lesser resistance where the syphilis virus makes its influence felt more intensely. When the auditory disturbances subside spontaneously or persist rebellious to renewed treatment of the syphilis, the assumption seems plausible that the trouble was predominantly the result of the toxic action of the arsenic, and that after elimination of the drug the changes were so slight that complete restitution followed or so severe that this was no longer possible. An argument in favor of this view is the benefit obtained in two cases by sweats and injection of pilocarpin to promote elimination of the arsenic, without further specific treatment. There is still a further possibility, namely, that the salvarsan may have sensitized the syphilitic virus. In his experience there were eighteen cases of neurorecurrences in the ear in which the interval since infection was only six to twelve months. The neurorecurrences were observed with both subcutaneous, intramuscular and intravenous injection of the salvarsan. In conclusion Mucha reiterates that these so-called neurorecurrences are serious matters for the patient and frequently entail permanent injury, and the patients seldom care for further medication. Mucha's material includes besides the eighteen ear cases, six with general toxic phenomena, digestive disturbances, intense headache and dizziness, six with disturbances in other cerebral nerves, four with epileptiform attacks, two with cerebrospinal phenomena, five with optic neuritis, one with optic neuritis plus cerebral hemorrhage leaving motor and mental disturbance, one case of fatal meningo-encephalitis, three cases of nonsyphilitic meningitis seemingly aggravated by the salvarsan, and a case of nephritis for which he thinks the salvarsan was evidently responsible, as distinct traces of arsenic were perceptible in the urine nine months after the intragluteal injection of salvarsan and the nephritis showed great improvement under sweating procedures. Twenty-four pages are devoted to the details of the forty-eight cases in which striking symptoms followed the salvarsan treatment out of the total 500 cases. Finger's previous comment on his experiences was summarized in these columns June 10, page 1765.

101 *Tincture of Iodin in Treatment of Surgical Tuberculosis. F. Franke.
102 *Double Opening in Gastro-Enterostomy. (Die neue Ruggi'sche Methode der doppelten Verbindungsöffnung zwischen Jejunum und Magen bei der Gastroenterostomie.) G. Rocchi and U. Stoppato.
103 *Early Diagnosis of Suppuration in and Around the Kidney. (Zur Frühdiagnose der paranephritischen Eiterung und des Nierenabszesses.) E. W. Baum.

101. **Tincture of Iodin in Surgical Tuberculosis.**—*Franke* states that he has been using *tincture of iodin systematically* for the last ten years in sterilization of the field of operation for tuberculosis of the soft parts. He fills up the cavity with the concentrated tincture and then removes the excess with a syringe after a minute or two, or if the cavity is small merely tampons with gauze which sucks up the excess. He has never seen any untoward by-effects, except in one case in which a small bone sequester interfered with healing, but as he had used other disinfectants in this case the iodin need not be incriminated. Since adopting this technic he has scarcely ever had to amputate on account of surgical tuberculosis, even in the elderly, and the success of the measure is instructively shown in the case of a woman of 43 finally cured after a series of operations including resection of the right knee and ankle, curetting from the ankle to the hip for ascending tuberculosis of the soft parts of the outside of the leg, with resection of nine ribs and of the lower half of the sternum.

102. **Double Gastro-Enterostomy Opening.**—Rocchi and Stoppato give an illustration of the two openings on the same plane, or nearly at right angles, which Ruggi prefers for gastro-enterostomy, in prevention of the vicious circle. The space between is at least 2 cm.

103. **Early Diagnosis of Suppuration in and Around the Kidney.**—Baum states that bacteria are found in the urine in case of metastatic suppuration in and around the kidney much more regularly than is generally recognized. He obtained positive findings in all but one of seven cases of the kind, while the urine was constantly sterile when the suppuration was retroperitoneal. Staphylococci are generally responsible for the suppuration and their toxins injure the epithelium in the canaliculi, rendering the walls permeable for the germs even when there are no cellular elements in the urine.

107. **Morbid Taste in the Mouth on Arteriosclerotic Basis.**—Müller's patient was a man of 52 who had had an intensely sweet taste constantly in the mouth for three weeks. Signs of pronounced arteriosclerosis were evident, but nothing was found to explain the taste anomaly except the arteriosclerosis. The nervous system seemed normal and no benefit was derived from bromids. Theobromin sodium salicylate (diuretin) was then prescribed and the effect was prompt and complete, the taste becoming normal the same day. On suspension of the drug the disturbance returned, but was again cured in the same way and the patient now takes this drug continuously and has been free from the trouble for a year. Similar benefit was realized in another case in which the patient complained of attacks of pain in the tongue, for which no cause except arteriosclerosis could be discovered.

117 Iridotasis. (Dr. Johan Borthen's "forbedring.") S. Holth.

112. **Fracture of the Radius.**—Nicolaysen discusses the lessons learned from thirty-five cases of fracture of the radius and five of dislocation without actual fracture, emphasizing various points by the aid of twenty-eight radiographs. The outcome, he reiterates, depends on correct reposition of the fragments and on the age of the patients. The result was ideal in all his patients under the age of 50 while it was satisfactory in only three of the ten over this age. The outcome was especially poor in an elderly patient with deforming arthritis.

113. **Acute Leukemia.**—Thue reports three cases with necropsy and compares the findings with the various prevailing theories in regard to acute leukemia and with some similar cases on record. His patients were three boys, 1, 5 and 16 years old. The bacteriologic findings were constantly negative.

114. **Lumbago.**—Hansen warns that persons with a tendency to lumbago should refrain from cold baths and fatiguing exercises. He has encountered cases in which the lumbago developed in connection with a series of gymnasium exercises. The chief characteristic of lumbago, he remarks, is the tendency to recurrence. In some cases the trouble is an unsuspected fracture of the transverse process of some vertebra. In other cases he has been able to discover a tender point in the psoas iliacus muscle on one side, palpating down from the attachment of the muscle on the trochanter. When this is the case, attempts to flex the thigh against resistance are painful. The old lumbago is thus revealed as having its seat not in the back but in the front. This discovery threw retrospective light on a number of puzzling cases in his practice. As with sciatica, the spine frequently shows curvature from the affected side, the affected muscle being relaxed as with rheumatic torticollis. In some cases of lumbago there is accompanying neuralgia in the pelvis, especially in the sciatic nerve, and this should be regarded in treatment. He advises examination during a free interval, seeking for the almost inevitable tender point, and until treatment succeeds in restoring normal sensibility here, there is little prospect of a permanent cure. Rest and warmth are the main factors, and he has the patient apply a hot water bottle to the seat of the sensitive point on retiring, taking internally at the same time 0.5 or 1 gm. acetylsalicylic acid. In very severe cases the patient should stay in bed. An orthopedic corset may be found useful and this or a plaster cast is absolutely necessary in traumatic lumbago; it may save the patient much trouble and discomfort later. Massage of the tender points is a further aid in treatment, but it should be done by skilled hands on a systematic plan, and repeated at intervals during two or three months. It should be commenced very gently, as, done carelessly, it may do more harm than good. The massage is most effectual with the patient reclining or partially reclining, with flexed knees.

115. **Tearing Away of the Tendon from the Patella.**—Andersen has had three cases of this kind in his practice during the last few years, the tendon of the quadriceps being torn smoothly from the patella. The rupture occurred during a backward fall, the muscle pulling the tendon out from its attachment to the patella. Three of the patients were over 70 and he did not venture to open the joint and suture the tendon in all of them, but it proved successful in the cases in which it was done. In each of the cases the patients had suffered the same accident a few years before on the other knee. Two of the patients said they had no pain at the time of the rupture. The outcome is seldom good without suture of the tendon, whether a plaster cast and massage are applied or not.

116. **Nail Extension for Fracture.**—Ingebrigtsen reports excellent results from application of extension in a compound fracture of the leg with the stumps lapping so that the leg was shortened by 1½ inches. A 15-pound weight was suspended from a Becker nail driven through the bones just above the malleoli, and the leg gradually assumed its normal length in three days while there was no pain after the extension was applied.

THE ADVANTAGES OF THE SO-CALLED DECORTICATION OF THE LUNG IN OLD EMPYEMA *

F. B. LUND, M.D.
BOSTON

In operating for an old empyema we are presented with the problem of closing an old, suppurating cavity with stiff, unyielding walls, the inner wall consisting of the lung with its thick covering of fibrous tissue and fibrin, the other wall being the wall of the chest cavity. It is obvious that to enable such an abscess cavity to close, either the bony framework must be removed from the chest wall, so that it may sink in against the lung, or the thick fibrous covering must be removed from the lung and the lung expanded so as to come in contact with the chest-wall, or a combination of these two methods must be affected. The old mutilating process, with which the names of Estländer and Schede are connected, consists of extensive multiple resection of the ribs, with or without the removal of the intercostal muscles, allows the skin of the chest and soft parts to fall in against the lung, and has for many years been known to present grave objections. In the first place, the mutilation was extensive, the operation was accompanied by a good deal of trauma, hemorrhage and shock, features which rendered it especially dangerous in patients weakened and exhausted by the chronic suppuration of an old empyema. In the second place, if it was performed in children during the growing period, the extensive removal of the chest wall would hardly fail to result in a curvature of the spine which, from lack of support of the ribs on the affected side would accentuate itself as the child grew and would be accompanied by increasing deformity.

In 1893, De Lorme in France and Fowler in America both hit on an operation which was designed to substitute for the mutilating operations of Estländer and Schede, and was planned to allow the lung to expand against the chest-wall, instead of letting the chest-wall fall in against the lung; this operation came to be called decortication of the lung. De Lorme noted that in old empyema the shrunken, contracted lung lay in the gully between the ribs and vertebra, covered and bound down by a thick, inelastic membrane consisting of partly organized fibrin and fibrous tissue. He thought that if a sufficiently large opening in the chest were made for the manipulations, and if this membrane were incised and peeled off the lung and removed, the lung might expand and fill the chest cavity, thus obviating the necessity of extensive removal of the chest-wall in order to accomplish his object. He cut a square flap, including the third to the sixth ribs, the base being at the anterior border of the scapula, the upper and lower margins following the ribs, and turned it backward in the soft parts as a hinge. He found the lung lying in the costovertebral angle, the lower surface of the cavity being the vault of the diaphragm, and the cavity extending to the apex of the lung. The parietal pleura was bound down with a membrane 1 to 1.5 cm. thick. He found the position of the lung impossible to define, it was so bound down by this membrane. He incised the membrane a hand's breadth behind the anterior chest-wall, in order to avoid the pericardium, going cautiously to avoid injuring the lung, using first the knife, then blunt scissors. On coming to the healthy lung, he enlarged the incision, peeled off the membrane and as the patient coughed, the middle lobe of the lung protruded through the opening, reached the chest-wall and even projected through the window he had made in it. This was repeated for the other lobes of the lung. After excising the visceral pleura, curetting and excising portions of the parietal pleura, the flap was put back and sutured around a drainage tube in the lower angle. He concludes, (1) that it is possible to free a lung from the membrane, which holds it down even long after an operation for empyema; (2) that the method is applicable not only on the right, but on the left, if one goes far enough behind; and (3) that this is better than Estländer's operation, because it expands and tends to restore the function of an otherwise useless lung. The great deformity and falling in of the chest-wall may be avoided. This, in young patients, might lead to spinal curvature.

At about the same time Fowler[1] of Brooklyn, operated on a woman, 35 years of age, who had a persistent sinus. He removed three and a half inches of five or six ribs and excised a mass of cicatricial ti[illegible]e sinus, and attached to the chest, [illegible]-cardium and lung. Hemorrhage was stopped by gauze pressure. There was considerable shock after the operation. The cavity was tamponed with gauze. The tampon was removed in twenty-four hours and a lighter one substituted. The cavity was irrigated and the gauze changed every day. The lung expanded and the cavity was closed in twenty-eight days. Thus, Fowler, with no special plan, apparently, of allowing the lung to expand by removal of the tough, fibrous covering, had at about the same time with De Lorme performed this operation. It seems to me that the credit of the operation should belong to De Lorme as he, apparently, had a definite plan to accomplish what he was after. To

[1] Fowler: Med. Rec., Dec. 30, 1903.

this valuable procedure of Fowler and De Lorme, has been applied the clumsy name of "decortication," from the Latin *cortex*, bark, meaning literally, barking or peeling off the bark from the lung. It is not, therefore, as a new procedure that I venture to take up this subject for discussion, but rather for the reason that so little has been written about it that I fear some of us may forget what a valuable resource it is and may, unnecessarily, perform severe mutilating operation when this simple operation would be safer and more effective.

Looking over the literature since that time, comparatively few reports of this operation are to be found. The same is true in regard to the operations of Estländer and Schede. I believe the reason for this to be, that in the primary operation for empyema, resection of the rib and provision of adequate drainage at the proper point has resulted in the cure of so many cases that few chronic cases result. Among the few reports in literature of the results of lung decortication, Charles M. Dowd[2] of New York, reports excellent results from decortication in old empyema in children. Ransohoff,[3] however, finds fault with the results of lung decortication, advising instead of decortication, the making of multiple incisions in the thickened pleura, thus allowing the lung to expand at numerous points. It does not seem to me that this method of multiple incisions can ssibly be as efficient as the free and complete removal e membrane and, as in my hands the free and com- removal of the membrane has been efficient, I ght it worth while to report my experience, which w amounts to seven cases.

Samuel Lloyd[4] of New York, who has had a very large experience in the treatment of empyema, chiefly in children, in a very interesting article given at the twenty-fifth anniversary of the New York Post-Graduate Medical School, states that in the treatment of old empyema it is not necessary to remove the pulmonary pleura, but simply to break up the adhesions at the borders of the cavity between the parietal and visceral pleura. This is undoubtedly true in early cases, and I believe that such adhesions should at the first operation of draining an empyema be so broken up. In the older cases, however, in which the membrane is thick, firm and rubber-like, it will easily be seen that it will be thickest and firmest at the point of attachment to the chest wall, so that it would be more difficult to break it at this point than where I have done it, namely, at a vertical line starting about the middle of the bottom of the cavity and extending upward along the lung. It is possible also that the lung might expand with this great, heavy, thick piece of membrane left on it. In the early cases, the lung would probably expand whatever is done to it, but in the old cases with this great, thick, leathery piece of membrane, the expansion of the lung could hardly be as complete and uniform from having its adhesions broken up at the edges, as it would from slitting it up in the middle and entirely separating it. Anybody who has felt with the finger and seen the wonderful expansion of the lung after the removal of this membrane, which is not a difficult procedure, will hardly advocate, in cases in which the membrane has any thickness at all, the method of simply breaking up the adhesions at the edges and leaving it on.

I think Lloyd's contribution to the subject is of great value, in that he emphasizes the point of removing at the primary operation a piece of more than one rib, if necessary, in order to get in more than two fingers to break up adhesions to the pleura, and this procedure was adopted in Case 7 of my series of cases, and I shall adopt it more often in the future. It cannot be said, however, to be absolutely essential in the early cases, and in the late cases I do not think it can be as satisfactory as the removal of the thick, leathery membrane or the old procedure of decortication.

In an experience of eighteen years at the Boston City Hospital, where I have operated in a fairly large number of cases of empyema, mostly, however, acute, although greatly interested in the question of lung expansion in these old cavities, I had no opportunity to operate for chronic empyema until April, 1907. This case, which was, briefly, that of a little girl of 14, who had had a sinus for a year, after the resection of the ninth rib in the posterior axillary line. I carried an incision upward, parallel to the anterior border of the scapula, resected portions of four ribs and found exposed a concave surface of the glistening membrane which bound the lung down in the gutter between the ribs and vertebra, so tightly that it hardly seemed as if there was any lung in the chest at all. On splitting this membrane with the scissors and separating it carefully from the surface of the lung, the lung began to expand and when the child coughed at the close of the operation the red, velvety lung blew up like a soap bubble and came up against the chest-wall, where it remained. The lower angle of the wound was drained. At first there was no discharge, until four or five days after when there was a slight discharge from the breaking down of the blood-clot which ran into the bottom of the chest. I show here pictures (Figs. 1 and 2) of the little girl four years later, after she had grown to be a young lady, and it can be seen that the chest-wall is excellently developed and there is no curvature of the spine.

The second case in which I employed this procedure was an old empyema following an extensive hemorrhage into the chest, hemothorax, resulting from a self-inflicted revolver wound. The patient had a sinus and a chronic discharge ten months after rib resection, for drainage of the infected blood-clot from his chest. In this case the same procedure was followed, the incision running upward and forward from the anterior end of the drainage incision. Five ribs were resected, the thick membrane covering the lung incised and peeled off with the finger, allowing the lung to expand. As the patient coughed, the lung expanded and nearly filled the cavity. A slight discharge persisted, and five months later I found a small cavity two inches in diameter, in the lower part of the chest which was cured by resecting a small portion of the rib. One month later, the wound healed up and has remained in excellent condition since. The patient was a thin, delicate man, who I feel sure would not have survived an extensive operation of the type of Estländer or Schede.

My next cases, 3, 4 and 5, were the result of what I believe to be misguided attempts to cure acute empyema by the method of Thiersch, advocated by Friedrich when he came to this country and spoke before this Association in 1898. He states that rib resection has been abandoned by him in recent, not circumscribed exudates, because, not here necessarily indicated, it requires a longer time and may be more dangerous through the onset of a pneumothorax.

Briefly stated, the method of Thiersch consists of a puncture of the chest-wall, insertion of a large trocar allowing the pus to escape, and the insertion of a Nelaton catheter of the same size as the trocar to which is attached a collapsible rubber tube which leads into a bottle of fluid at the side of the bed. The Nelaton catheter is fixed air-tight to the chest-wall by the use of rubber tissue and adhesive plaster. The theory is, that when the patient expires, the pus runs out through the tube and on inspiration the collapsible walls of the tube are sucked together and prevent the entrance of air and cause negative pressure in the chest, favoring expansion of the lung. This is one of the numerous methods of securing negative pressure in the chest, the first of which, I believe, was adopted by Bülau; the others have been advocated by Perthes, Van Hook, and numerous other writers. In many of them, a current of running water supplied by a Bunsen pump, is employed to cause constant suction of the chest. The use of all these methods is based on what seems a well-founded objection in methods of rib resection and leaving a wide opening, namely, that such an opening allows the free entrance of air into the chest, which tends to press on the surface of the lung to prevent its expansion resulting in chronic pneumothorax and chronic empyema. The last, and probably the most efficient, of these suction methods is that advocated by Robinson of Boston, which consists in trephining the rib and screwing in a threaded metal tube, to which the rubber tube is attached, thus furnishing an absolutely air-tight connection between the chest-wall and the tube. The objection to all these methods, to my mind, is that, while they do provide an air-tight connection for a very short time, the opening made is necessarily small and the masses of fibrin which are so often found in the cavities cannot be removed, and when the tube has finally to be removed, as it always has, the small opening closes over so quickly that a little pus is apt to be left behind, and the case becomes chronic or requires reoperation.

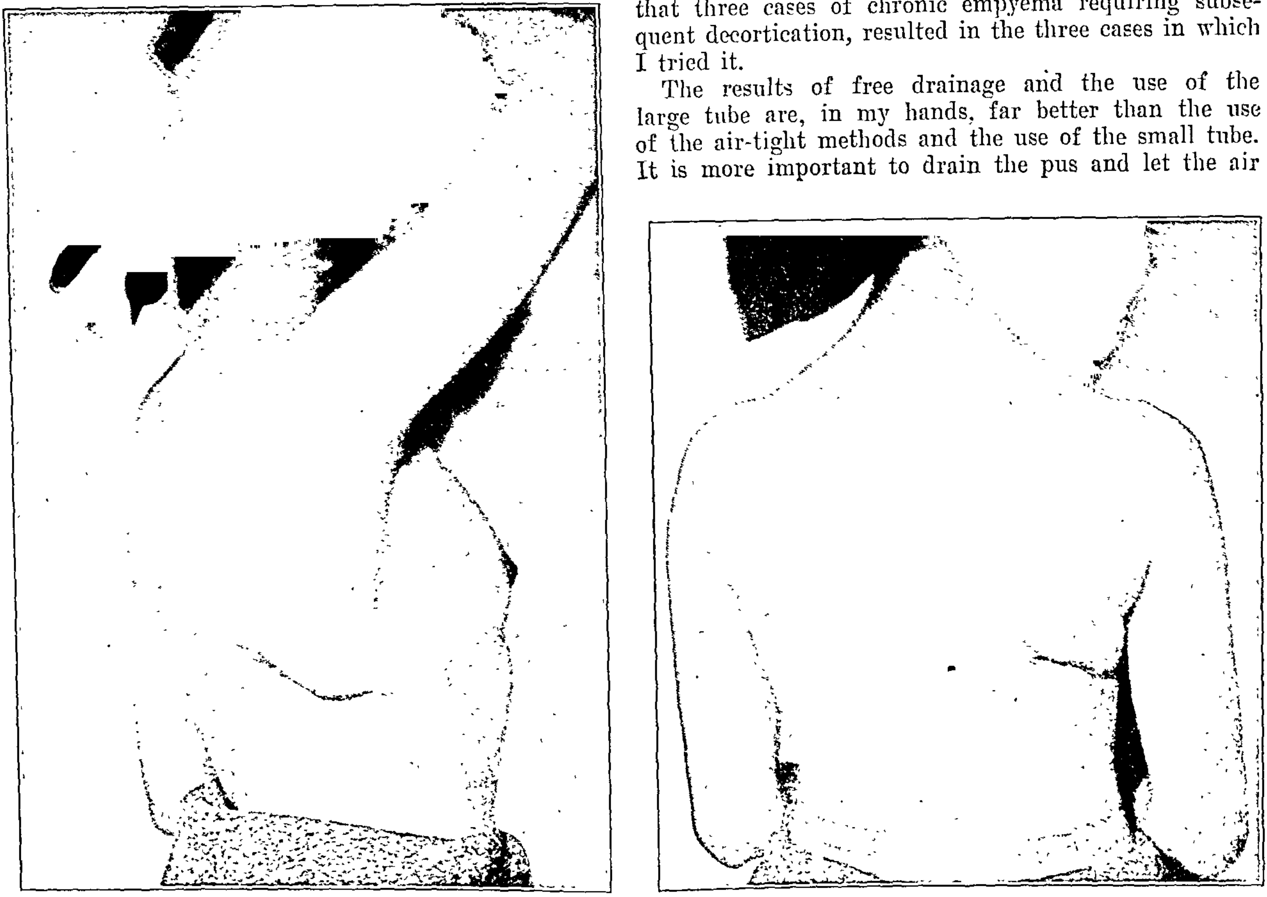
[4] Lloyd, S.: The Treatment of Unresolved Pneumonia, in Science of Medicine and Surgery, 1908, p. 177.



Figs. 1 and 2.—Patient, 18 years old, four years after operation for chronic empyema. Note the development of chest-wall and the fact that there is no curvature of spine.

As stated above, in an experience covering eighteen years and a fairly large number of cases, I have almost invariably treated empyema by resection of two or three inches of the ninth or tenth ribs in the posterior axillary line and the insertion of a large tube. Doubtless, in some of these cases, the lesions have failed to heal and have become chronic, but at all events, patients have not come back to me for treatment. It is an interesting commentary on Thiersch's method, at least in my hands, that three cases of chronic empyema requiring subsequent decortication, resulted in the three cases in which I tried it.

The results of free drainage and the use of the large tube are, in my hands, far better than the use of the air-tight methods and the use of the small tube. It is more important to drain the pus and let the air take care of itself than to try to keep out the air at the expense of free drainage of the pus and fibrin. No matter if the air does enter the thorax at first, it is frequently soon prevented from entrance by the pressure of the thick pus-soaked dressing over the end of the tube, which in itself provides a very fair valve, and I believe that the expansion of the lung is more frequently prevented from the reaccumulation of pus from insufficient drainage than by the entrance of air through a large opening.

Patient 3 was a man of 34, on whom Thiersch's method of drainage was attempted in January, 1910. Seven weeks later he had a free discharge and a large cavity treated by resection of five ribs and decortication. The cavity was of good size, entirely lined by thick, tough membrane. The membrane was split vertically over the lung and peeled back and the cavity partially filled it. The patient went home one month after the operation with a sinus, went to work and worked for nearly a year, but returned January, 1911, with a reaccumulation of pus and a large cavity. I operated again and this time found the membrane very adherent to the surface of the lung which failed to expand after its removal, therefore an extensive resection was done to six ribs allowing the chest-wall to fall in on the lung. A few days later, the patient died of septicemia. Although the decortication in this case was not successful, I feel that, had an extensive rib resection been done in the first place, the patient would have died just one year sooner. The patient had valvular heart disease.

In Case 4 the empyema was drained by Thiersch's method, except that rib trephining was adopted instead of trocar puncture. Six weeks later, after the discharge from the hospital, however, the patient returned with his chest full of pus again and a sinus. In this case, the sinus was on the left side of the chest, and the incision in the membrane for decortication had to be carefully made behind the pericardium. The lung expanded and filled the cavity. Two large tubes, surrounded by gauze, were placed in the lower angle of the wound for drainage. There was very little shock. The gauze and tubes were all removed on the second day, and all the drainage was removed on the eleventh. The patient made an excellent recovery and regained complete expansion of the lung without deformity of the chest or curvature of the spine.

In Case 5, the patient was a delicate man, 20 or 21 years of age. Thiersch's method was applied in a metapneumonic empyema. Three weeks later the patient was running a high temperature; drainage was unsatisfactory and there was a large cavity. Decortication was performed as in the preceding cases. The lung, as in the former cases, came out and filled the cavity. This operation was attended by a good deal of shock. The temperature gradually returned to normal. The lung, however, did not in this case stay up against the chest-wall, and the patient began to have cough and expectoration. He died six weeks after the decortication, apparently of pneumonia of the opposite lung. He was thought by consultants to have tuberculosis, but no tuberculous bacilli were found in the sputum and no autopsy was obtained. In this case, also, although the result was unsatisfactory, I cannot but feel that a more promptly fatal result would have followed an extensive removal of the ribs.

Patient 6 was a middle-aged woman in whom, contrary to my usual custom, a rib resection had been made in the midaxillary line, thus failing to provide adequate drainage in the recumbent and sitting positions. Chronic empyema resulted and decortication was done six months later by the method previously described. The lung expanded well and recovery, though delayed by the slipping in of a drain which was inserted by the physician in charge during convalescence, was complete as soon as this drain was removed at the third operation.

The seventh case was one of abscess of the lung with pyopneumothorax which had existed six weeks and in which, at the primary operation, the lung was found so bound down and covered by the thick membrane that it was thought wise to decorticate it at the time. The operation was completely successful, and the patient made a rapid decovery. A crater-like ulcer on the surface of the inferior lobe was, to my mind, a very interesting finding.

It will be seen that two of these seven cases were fatal. Neither of them, however, was fatal from shock, and I think the same result would have followed any method of treatment.

Beck's method of filling chronic empyema sinuses with bismuth paste has not seemed to me applicable in cases with very large cavities, say two-thirds or three-quarters of the entire pleura and, personally, I have had rather poor results with the insertion of any kind of foreign material in an infected cavity.

In regard to the technic of the operation, the method of the resection of 1½ inches of five or six ribs, through an incision running upward and forward from the anterior end of the old drainage incision, has proved, to my mind, very satisfactory. In slitting up the thickened pleura beneath the ribs, I have had in one or two cases, to grab the intercostal artery, but have been very much surprised to find how little trouble there has been from bleeding. The visceral pleura, which is about a quarter of an inch thick and which is more like the sole of an old rubber shoe than anything else, is carefully incised with a knife over the lower part of the lung. The finger is inserted through the incision and as soon as the soft surface of the lung is felt, is swept to and fro with the pulp of the finger toward the pleura and pressing outward so as to cause the least possible damage to the lung. Then a pair of blunt-pointed scissors is inserted and the membrane slit clear up to the top of the chest, and cleared off from the lung with the finger. A wound of one or two of the air-cells resulted in two or three of my cases, allowing the escape of bubbles of air on exploration, but so small an area of the lung was affected that, apparently, no harm resulted.

In regard to the after-treatment, it is probable that after the patient is put to bed, the lung does retract to a certain extent, but the occasional coughing keeps up the expansion. The thick, pus-soaked dressing, if tightly applied, to my mind, acts as a more efficient valve than any mechanical valve which one could employ. Certainly, in most of my cases, expansion of the lung was marvelously preserved, and in Case 5 I think that failure may have been due to the dressing failing to give us an efficient valve. Change of dressing should be accomplished as rapidly as possible and the tubes removed early; in most instances, I think, on the second or third day.

In the majority of cases, the lung is driven inward so that it extends from the top to the bottom of the chest and at its base is adherent to the diaphragm. This adhesion to the diaphragm, in this class of cases, will have to be broken up in addition to the removal of the membrane covering the lung. In some of the cases, however, the lung, instead of being driven in, is driven both inward and outward, so that it lies contracted along the upper inner wall of the pleura. In these cases, removal of the membrane covering it will be entirely sufficient and there will be no diaphragmatic adhesions to be attended to.

It is possible that an intercostal incision and the use of the modern rib retractor may simplify this operation, but as the incision in the pleura has got to be in the long axis of the lung, it seems to me that multiple rib resection would be better. I have not had an opportunity to employ either positive or negative pressure as an aid in these operations and do not believe that it is necessary if, as should always be done, the ether is taken off as early as possible, and the patient allowed to cough at the moment that the membrane has been stripped off the lung. This facilitates expansion in a wonderful manner. The intratracheal insufflation method of Melzer and

Auer, I believe, will be a distinct aid in these lung cases. One feature which renders it valuable is that it is possible to blow all the ether out of the lung with fresh air at the close of the operation, so that the patient almost immediately comes out. I have not had an opportunity to employ this method myself as yet, but intend to do so at the earliest opportunity. My colleague, Dr. Nichols, has employed this method in one case of decortication and states that he was astonished at the way the lung expanded and filled the cavity when the visceral pleura was removed. His patient made an excellent recovery.

PLASTIC OPERATIONS ON THE FACE*

J. SHELTON HORSLEY, M.D.
Professor of Principles of Surgery and Clinical Surgery in the Medical College of Virginia; Surgeon to Memorial Hospital
RICHMOND, VA.

Surgical operations are usually designed to save life or to increase function. Even plastic operations on other parts of the body than the face have as their chief object the restoration of function. Operations on the vaginal outlet are performed for the purpose of correcting malpositions of the uterus or of returning the bladder and rectum to their proper position and so rendering these organs better able to functionate normally. Plastic operations on the hands or feet for deformities, on the bowel or bladder for fistulous openings, or on the throat or mouth for congenital defects, are intended to restore to usefulnss the parts affected. Plastic operations on the face, however, are done chiefly for their cosmetic effect, as the function of no organ is materially altered by the facial deformities which such operations are designed to correct.

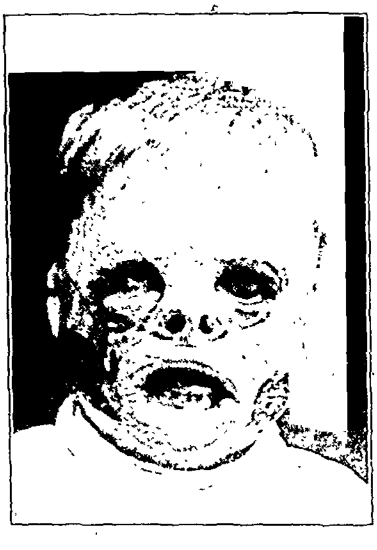

Fig. 1.—J. M., aged 10. Deformity of the face from burn; from photograph taken two days before first operation.

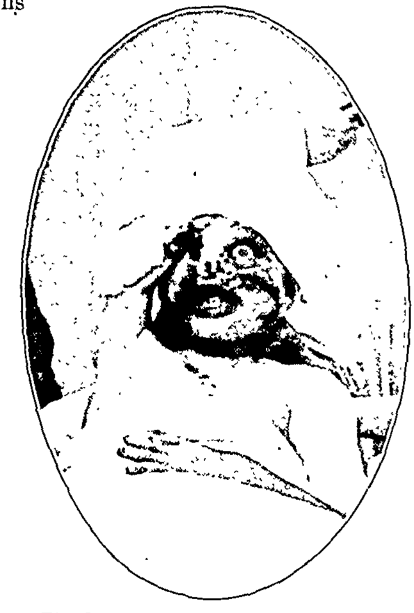

Fig. 2.—J. M., after lower lip and part of the uper lip had been formed from a flap taken from the left shoulder and arm. A flap is now being transferred from his right arm to cover the right eye. The eyelashes have been shaved and the eyelids closed by suture so the flap is transplanted over both lids at one time.

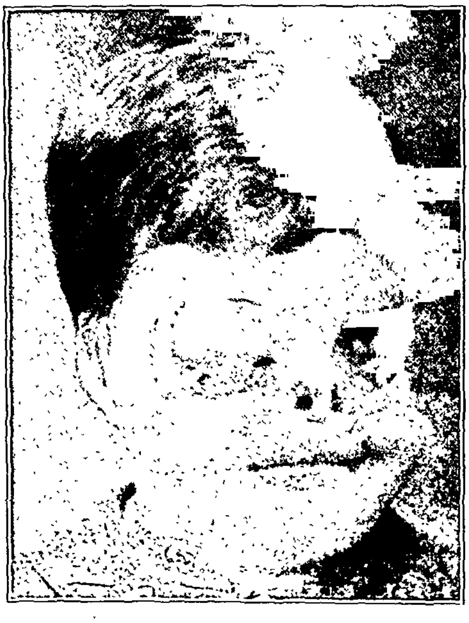

Fig. 3.—Patient J. M. a few days after flap had been cut from its base on the arm.

While the correction of facial deformities cannot be classed as life-saving, such procedures when successful benefit not only the patient, but the community. An operation for appendicitis, for instance, may save an individual life, but usually few outside of the patient's friends and relatives care anything about it. But the surgeon who corrects a cicatricial contraction about the face or operates on a bad double harelip should have the gratitude of every one who has had to see these unfortunate patients, and is at least as much of a public benefactor as the proverbial philanthropist who causes two blades of grass to grow where only one grew before.

This branch of surgery, then, has to do with improving the patient's personal pulchritude, and the length of the incision, the position of the scar, and the coaptation of the skin are of prime importance instead of being as in most operations matters of secondary consideration. Herein plastic operations on the face differ both in technic and in results from other surgery.

Deformities which make plastic operations on the face necessary may be classed under three heads: First, congenital deformities, of which the most common is harelip; second, deformities produced by injury or disease, which may be subdivided into contractions following ulcers or burns and mechanical trauma; third, deformities that result from operations for removal of cancer or lupus. This third group differs somewhat from the second. Though it may be said to occur as the result of disease, the immediate defect is one that has been purposely made by the surgeon under aseptic precautions and, in a manner, he may control the character of the defect. No operation for cancer should ever be done with any other object in view than complete extirpation of the cancerous mass; still at times the incisions may be so shaped as to make a resulting wound that will not leave an unsightly scar while sacrificing nothing to thoroughness.

Without attempting to give a detailed report of cases, I shall describe some operations and results that may serve to illustrate the second two of these three different classes of cases that have been grouped under the heading of plastic operations on the face.

Deformities produced by disease, and particularly by burns, are peculiar from their marked tendency to con-with a sinus, went to work and worked for nearly a year, but returned January, 1911, with a reaccumulation of pus and a large cavity. I operated again and this time found the membrane very adherent to the surface of the lung which failed to expand after its removal, therefore an extensive resection was done to six ribs allowing the chest-wall to fall in on the lung. A few days later, the patient died of septicemia. Although the decortication in this case was not successful, I feel that, had an extensive rib resection been done in the first place, the patient would have died just one year sooner. The patient had valvular heart disease.

PLASTIC OPERATIONS ON THE FACE*

J. SHELTON HORSLEY, M.D.
Professor of Principles of Surgery and Clinical Surgery in the Medical College of Virginia; Surgeon to Memorial Hospital
RICHMOND, VA.

Surgical operations are usually designed to save life or to increase function. Even plastic operations on other parts of the body than the face have as their chief object the restoration of function. Operations on the vaginal outlet are performed for the purpose of correcting malpositions of the uterus or of returning the bladder and rectum to their proper position and so rendering these organs better able to functionate normally. Plastic operations on the hands or feet for deformities, on the bowel or bladder for fistulous openings, or on the throat or mouth for congenital defects, are intended to restore to usefulness the parts affected. Plastic operations on the face, however, are done chiefly for their cosmetic effect, as the function of no organ is materially altered by the facial deformities which such operations are designed to correct.

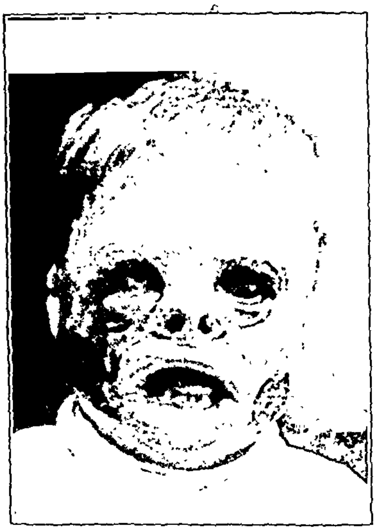

Fig. 1.—J. M., aged 10. Deformity of the face from burn; from photograph taken two days before first operation.

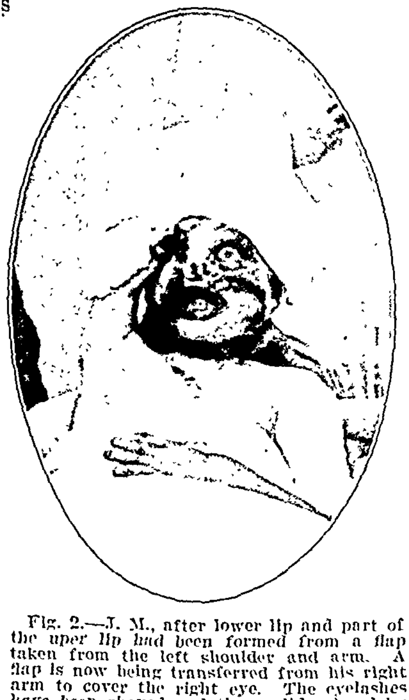

Fig. 2.—J. M., after lower lip and part of the uper lip had been formed from a flap taken from the left shoulder and arm. A flap is now being transferred from his right arm to cover the right eye. The eyelashes have been shaved and the eyelids closed by suture so the flap is transplanted over both lids at one time.

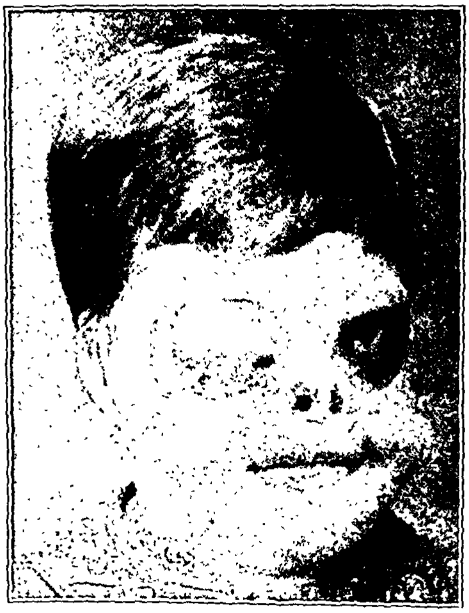

Fig. 3.—Patient J. M. a few days after flap had been cut from its base on the arm.

While the correction of facial deformities cannot be classed as life-saving, such procedures when successful benefit not only the patient, but the community. An operation for appendicitis, for instance, may save an individual life, but usually few outside of the patient's friends and relatives care anything about it. But the surgeon who corrects a cicatricial contraction about the face or operates on a bad double harelip should have the gratitude of every one who has had to see these unfortunate patients, and is at least as much of a public benefactor as the proverbial philanthropist who causes two blades of grass to grow where only one grew before.

This branch of surgery, then, has to do with improving the patient's personal pulchritude, and the length of the incision, the position of the scar, and the coaptation of the skin are of prime importance instead of being as in most operations matters of secondary consideration. Herein plastic operations on the face differ both in technic and in results from other surgery.

Deformities which make plastic operations on the face necessary may be classed under three heads: First, congenital deformities, of which the most common is harelip; second, deformities produced by injury or disease, which may be subdivided into contractions following ulcers or burns and mechanical trauma; third, deformities that result from operations for removal of cancer or lupus. This third group differs somewhat from the second. Though it may be said to occur as the result of disease, the immediate defect is one that has been purposely made by the surgeon under aseptic precautions and, in a manner, he may control the character of the defect. No operation for cancer should ever be done with any other object in view than complete extirpation of the cancerous mass; still at times the incisions may be so shaped as to make a resulting wound that will not leave an unsightly scar while sacrificing nothing to thoroughness.

Without attempting to give a detailed report of cases, I shall describe some operations and results that may serve to illustrate the second two of these three different classes of cases that have been grouped under the heading of plastic operations on the face.

Deformities produced by disease, and particularly by burns, are peculiar from their marked tendency to contraction. Thiersch's grafts do not prevent contraction after a burn. The effort by Nature to reproduce a corium results in reformation of cicatricial tissue and while the raw surface may be covered by the epithelium of the grafts the contraction recurs in time as bad as it was before. The whole thickness of the skin must be transplanted in places where contraction is to be avoided. This may be done by the Krause or by the Wolfe method of transplanting strips of the whole thickness of the skin taken from the thigh or other portions of the body. As these strips require more nourishment than the thin Thiersch grafts the pieces have to be smaller, as the vessels may enter and nourish a small strip of skin, whereas a larger piece would die. This method cannot be used satisfactorily in extensive deformities produced by burns about the face, as the scars that form between the strips are very unsightly. A boy, whose picture I present (Figs. 1 to 5), was burned by the explosion of a keg of powder about six months before he came under my treatment. Contraction was so great that the mouth could not be closed and saliva constantly dripped over his clothing. There were raw ulcers on the cheeks which would not heal and the eversion of the eyelids from the contraction gave the patient a most repulsive appearance. The lips were freed and the scar tissue dissected away down to the muscles. Care must be taken in such cases to dissect away all of the connective tissue and at the same time not to go deep enough to injure the filaments of the facial nerve. The lips were built up by a flap taken from the arm and shoulder,

---

* Read by invitation at the meeting of the South Carolina Medical Association, Charleston, S. C., April 19, 1911.

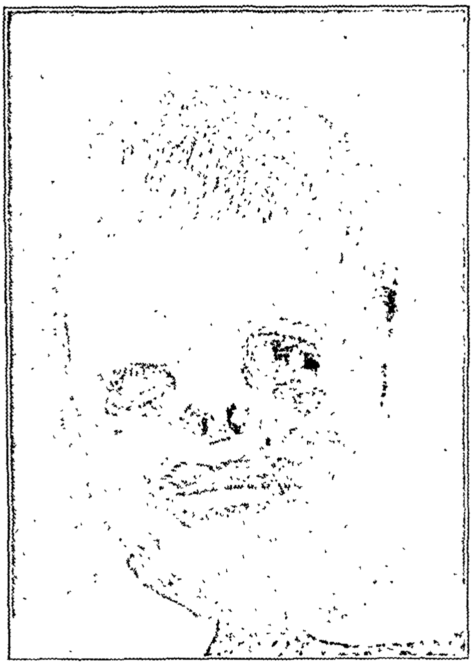

Fig. 4.—J. M.; flap over the eyes has been divided and stitches removed. The upper eyelids were satisfactory, but there was not enough of tissue on lower lid to prevent eversion. Another flap was taken, which is shown in Figure 5.

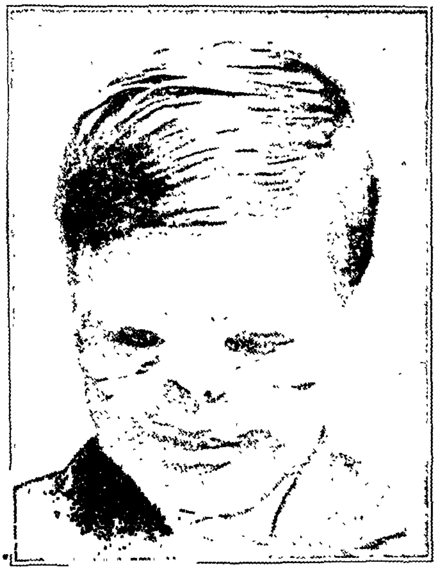

Fig. 5.—Patient J. M. after twenty operations had been performed on him. Both upper and lower eyelids have been satisfactorily built up from flaps from the arm and by Wolfe's grafts from the thigh.

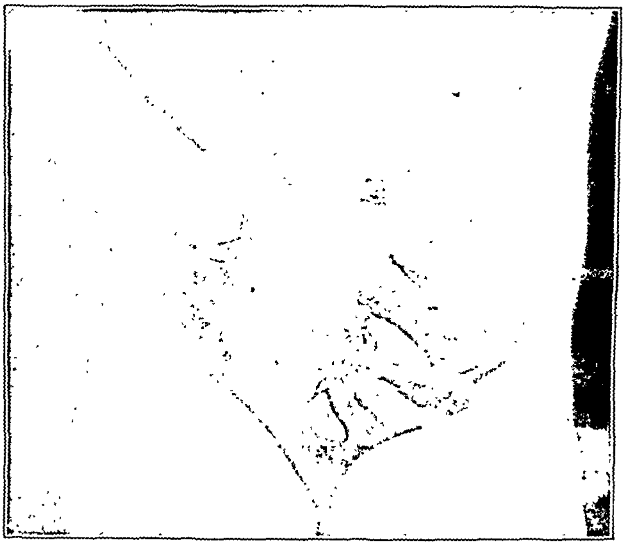

Fig 6.—Method of using skin from the back of the hand for correcting deformities and remedying defect on hand by replacing whole skin from the abdomen.

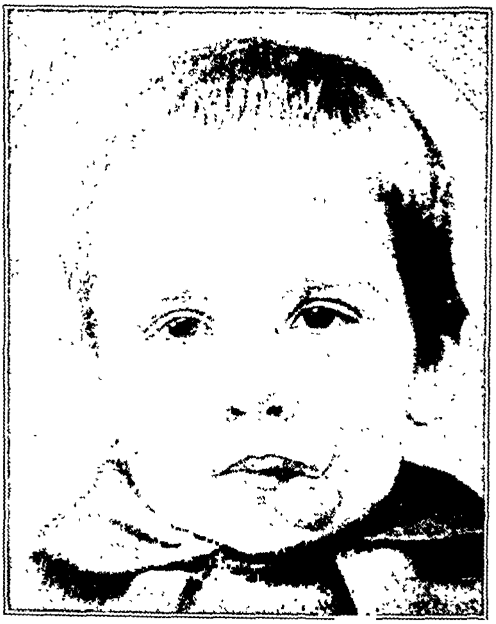

Fig. 7.—R. E. Noma following typhoid fever. The left half of lower lip, mucous membrane a[illegible] of jaw-bone sloughed away, so the under[illegible] ould be seen through defect. The *photograph* [illegible] *operation in* which lip was built up by a quadrilateral flap from the cheek which was turned into the defect.

which was sutured in position with the base of the flap attached to the arm and the arm fixed over the head for ten days with plaster of Paris. The base of the flap was then cut away. After a long series of operations the deformities were mostly overcome. They were remedied chiefly by taking flaps from various portions of the arm in the manner just described and partly by transplanting whole pieces of skin to fill out small defects. Flaps of skin may be transplanted from any portion of the body by first attaching them to the hand, then cutting away the flap and transplanting this to the face or by first using the skin on the back of the hand and then covering the defect in the hand with whole skin from the abdomen (Fig. 6).

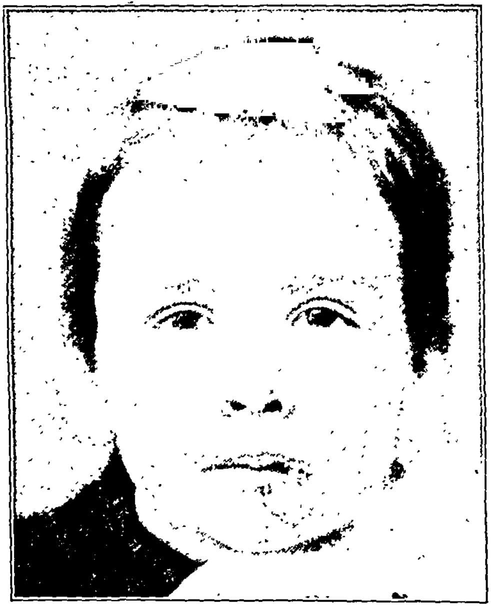

Fig. 8.—R. E., from photograph taken soon after a flap of mucous membrane was raised and attached to the newly constructed lip to form a vermilion border.

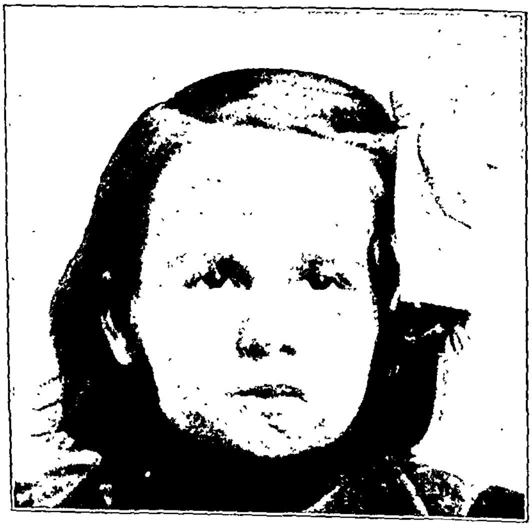

Fig. 9.—R. E., from a photograph taken about one year after second operation.

Diseases such as noma produce very unsightly defects and are best corrected by transplanting flaps from the immediate neighborhood if possible. In one case (Figs. 7, 8 and 9) half of the lower lip with the underlying bone and mucous membrane sloughed away as the result of noma. This was repaired by a quadrilateral flap from the cheek, which was turned into the defect. Later a flap of mucous membrane from the inside of the lip formed a very satisfactory vermilion border. In such instances the problem of contraction does not materially affect the result.

Another case (Figs. 10 and 11) presents a rather unusual deformity which resulted from a fracture of the frontal bone and a sloughing away of the anterior wall of the frontal sinus. This left a marked defect which exposed the frontal sinus and made a deep cavity in the forehead. After finding that the communication between the floor of the frontal sinus and the nose was open, two small flaps were turned in from the margins of the defect so that the skin surface formed the anterior wall of the frontal sinus. This corrected the depression and a U-shaped flap taken from the forehead covered the raw surface of the flaps that had been turned in. The defect left by this flap was corrected by undermining the skin and sliding it over. The result is shown in Figure 11.

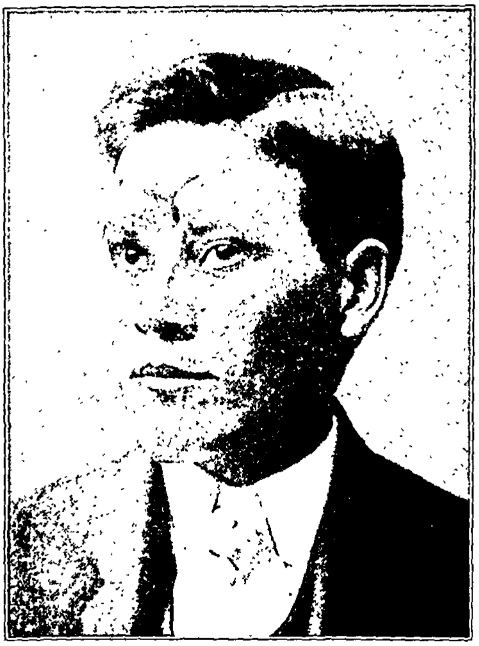

Fig. 10.—E. W. S., from photograph taken before operation, showing defect following fracture of frontal bone and sloughing away of anterior wall of frontal sinus.

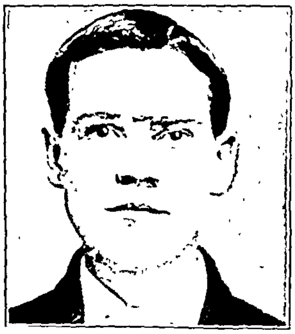

Fig. 11.—E. W. S., from photograph taken about eight months after operation.

The principles which might be said to underlie plastic operations of the face are, first of all, a careful mapping out of the procedures necessary to correct the deformity traction. Thiersch's grafts do not prevent contraction after a burn. The effort by Nature to reproduce a corium results in reformation of cicatricial tissue and while the raw surface may be covered by the epithelium of the grafts the contraction recurs in time as bad as it was before. The whole thickness of the skin must be transplanted in places where contraction is to be avoided. This may be done by the Krause or by the Wolfe method of transplanting strips of the whole thickness of the skin taken from the thigh or other portions of the body. As these strips require more nourishment than the thin Thiersch grafts the pieces have to be smaller, as the vessels may enter and nourish a small strip of skin, whereas a larger piece would die. This method cannot be used satisfactorily in extensive deformities produced by burns about the face, as the scars that form between the strips are very unsightly. A boy, whose picture I present (Figs. 1 to 5), was burned by the explosion of a keg of powder about six months before he came under my treatment. Contraction was so great that the mouth could not be closed and saliva constantly dripped over his clothing. There were raw ulcers on the cheeks which would not heal and the eversion of the eyelids from the contraction gave the patient a most repulsive appearance. The lips were freed and the scar tissue dissected away down to the muscles. Care must be taken in such cases to dissect away all of the connective tissue and at the same time not to go deep enough to injure the filaments of the facial nerve. The lips were built up by a flap taken from the arm and shoulder,

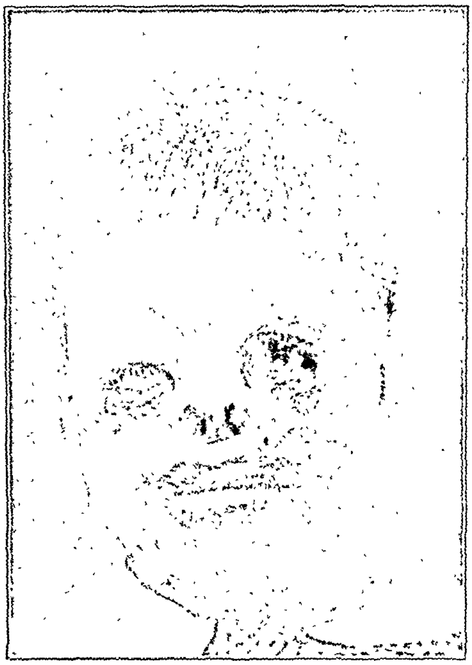

Fig. 4.—J. M.: flap over the eyes has been divided and stitches removed. The upper eyelids were satisfactory, but there was not enough of tissue on lower lid to prevent eversion. Another flap was taken, which is shown in Figure 5.

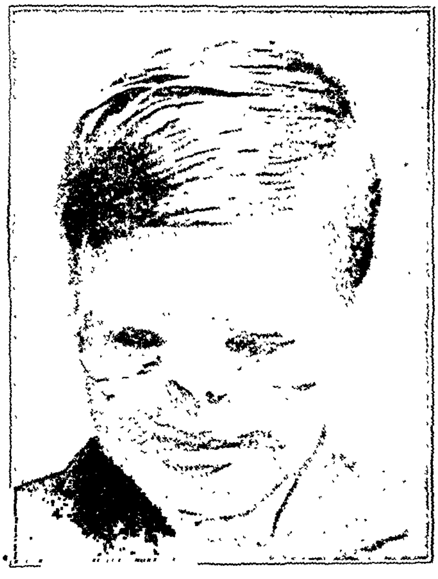

Fig. 5.—Patient J. M. after twenty operations had been performed on him. Both upper and lower eyelids have been satisfactorily built up from flaps from the arm and by Wolfe's grafts from the thigh.

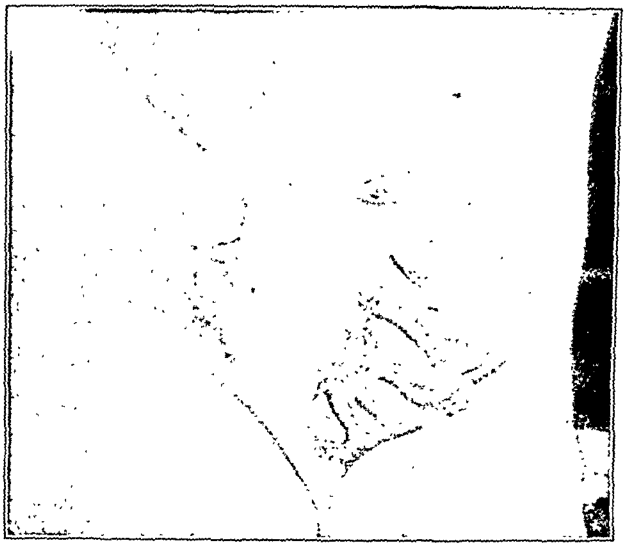

Fig. 6.—Method of using skin from the back of the hand for correcting deformities and remedying defect on hand by replacing whole skin from the abdomen.

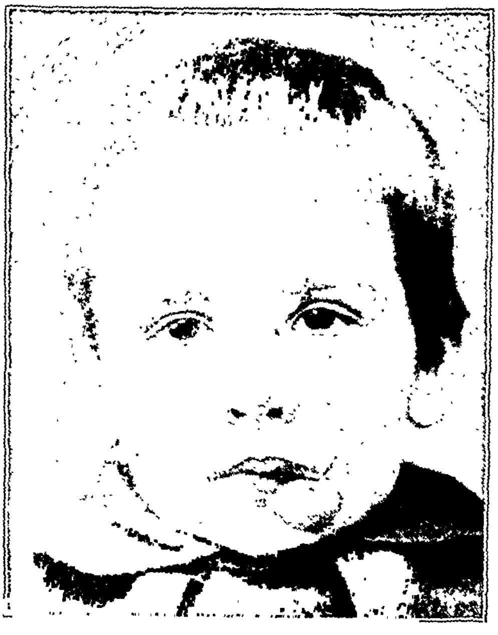

Fig. 7.—R. E. Noma following [illegible]. The left half of lower lip, mucous membrane and underlying portion of jaw-bone sloughed away, so the under surface of tongue could be seen through defect. The photograph was taken after first operation in which lip was built up by a quadrilateral flap from the cheek which was turned into the defect.

in each case. Asepsis cannot be maintained and prompt healing will occur only when the tissue is properly nourished and gently handled. Rough handling or lack of consideration for the nutrition of the flaps will result disastrously no matter how accurately the defect is covered. The flaps should always be taken a little larger than seems necessary, particularly in remedying deformities resulting from burns. No dressing should be placed on these wounds unless there is considerable bleeding; in this case a dry compress may be used for twenty-four hours and should then be removed. The raw surface should be dusted with boric acid powder, which forms a scab, and usually quick healing results. If a dressing is put on these wounds the secretion from the nose, mouth or eyes will be absorbed by the dressing and a septic poultice results, whereas antiseptic scabs are formed by incorporation of antiseptic powder into the coagulated serum and the wound is soon sealed and protected from the air. The suturing should be accurate, not tight enough to constrict, but tight enough to approximate the surfaces closely. I use a fine curved reversed Hagedorn needle and fine silk, which leaves the most inconspicuous scar. Where tension is great silkworm-gut is employed as the main suture for harelip operations. Sutures should be removed as soon as possible. In harelip where there is considerable strain on the stitches they have to be left longer than in operations where there is no tension, but here some of the stitches can be removed in six days and all should be out within eight or nine days. In other locations the stitches can usually be removed in five days. No plaster or other dressing should ever be placed on the harelip wound, but relief of tension on the sutures can be secured by two strips of adhesive plaster, which run from the cheek across the nose to the opposite side of the forehead. When these are drawn tightly, complete relaxation of the upper lip is obtained.

421 West Grace Street.

A METHOD FOR GRADUAL AUTOMATIC OCCLUSION OF THE LARGER BLOOD-VESSELS AT ONE OPERATION *

J. M. NEFF, M.D.
SPOKANE, WASH.

Stimulated by the work of Halsted and Matas, I and my assistants recently undertook some experiments with the object of working out a method for the gradual automatic occlusion of the larger blood-vessels at one operation.

Halsted used aluminum bands on the arteries for the purpose of permanently occluding their lumina, completely or in part, while Matas employed them for testing the efficiency of the collateral circulation. In neither of these methods, however, nor in any other that we know of, is there any definite and well-directed attempt to bring about gradual automatic occlusion in one operation, the thing above all others needed in arterial surgery for the treatment of aneurysm and tumors involving the great vessels.

It was for the purpose of establishing a principle, which might be at least a step toward the solution of this problem, that we devised the clamp described below. In the larger number of our experiments, we used the clamp called Model 2 (shown in Figures 1, 2 and 3), because of its simplicity of construction and application. It consists of two pieces of sheet aluminum, No. 13 B. & S. sheet metal gauge, hinged at one end as shown in Figure 1. For the common carotid artery of the dog, each blade is 5/16 inch wide and 7/8 inch long. The edges of the opposing surfaces of the blades are carefully rounded off, so that they will not injure the vessel which passes through the space (*c*) of the clamp. The deep groove (*f*) in the end of each blade, is for the catgut which is wound in layers in one or both of them and serves to separate the blades after the clamp is applied to the vessel. The short set-screw (*c*) was incorporated in the clamp in the early part of the work, for the purpose of preventing the blades from coming together, and thus cutting through the vessel after the catgut was absorbed. We now consider the set screw unnecessary and believe that gradual complete occlusion and division of the vessel is the ideal result.

The grooves (*d*) next to those for the catgut are for a rubber elastic band, the purpose of which is to approximate the two blades during the gradual absorption of the catgut. The elastic, therefore, must be of the very best dental ligature material to tolerate encapsulation under tension for a prolonged period of time.

Next to the hinge (*a*) are the shallow grooves (*b*) for a second rubber band. The object of this band is not so much to draw the blades together as to prevent the artery from slipping into the narrow part of the clamp next to the hinge. Figure 2 shows the clamp on the flat with grooves for the rubber bands and catgut.

Figure 3 shows the clamp with artery (*c*), rubber bands (*b* and *d*) and catgut (*e*) in position.

APPLICATION

The application is exceedingly simple. The clamp and rubber bands are sterilized by boiling, and No. 1 plain sterile catgut is wrapped in the end groove of one of the blades. This must be carefully done, three or four layers being placed one on the other in the groove. The ends of the gut are then tied together on the outer surface of the blade. The clamp is now applied to the artery and the blades pressed together as closely as the catgut will permit. If the pulsation distal to the clamp is markedly weakened, the latter is removed and two or three layers of gut wrapped in the end groove of the other blade. The clamp is again applied to the artery (Fig. 3), and two turns of No. 9 dental elastic band (*d*) are placed around both blades in the groove. A section of small-sized rubber tubing or a single turn of No. 9 elastic band (*b*) is slipped over the hinged end, the muscles and fascia then sutured with catgut over the clamp and the operation is complete.

MODUS OPERANDI

The principle underlying the action of the clamp is the gradual absorption of the catgut between the ends of the blades and the consequent gradual automatic approximation of these blades by the elastic bands. The artery in the grasp of the clamp is necessarily gradually occluded as the blades come together, the occlusion taking place so slowly that the collateral circulation has an opportunity to develop. After the catgut has completely absorbed and the blades are together, all tissue in the grasp of the clamp undergoes pressure atrophy and is absorbed. This we consider an ideal result: the vessel cut in two and occluded by the clamp, each of the ends tapering to a point and united by a cord of firm fibrous tissue.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

We have learned from our experiments that the catgut is entirely absorbed in from three to four weeks and that the ideal result mentioned above is obtained in the majority of cases.

We do not know whether the portion of catgut between the blades is actually absorbed or slips out layer by layer, coincident with the absorption of each layer on the surface. The same result, however, is brought about in either case, viz., the gradual approximation of the two blades, by the rubber band as each successive layer of gut is absorbed.

Model 1 (shown in Figure 4), with catgut wound around the ends of one or both blades, or decalcified bone between the blades, transfixed by a pin to prevent its displacement, was used in most of our early experiments. The rubber elastics have practically the same arrangement as in Model 2, except that there are no definite grooves for them or the catgut. We believe that catgut is superior to decalcified bone as a separating agent, because it can be applied to the blades in layers, thus giving greater assurance of gradual absorption. A decided advantage of Model 2 is the deep groove for the catgut. This deep groove (*f*, Figure 1), with the end flange partly filed off, gives a narrow shank on which to wind the gut, affording a minimum surface between the blades, where absorption is slow and uncertain, and a maximum outer surface where absorption readily occurs.

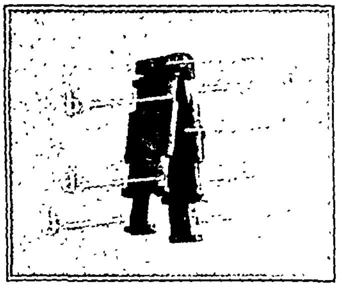

Fig. 1.—Clamp model 2; a, hinge; b, groove for rubber band; c, space for artery; d, groove for rubber band; e, set screw; f, groove for catgut.

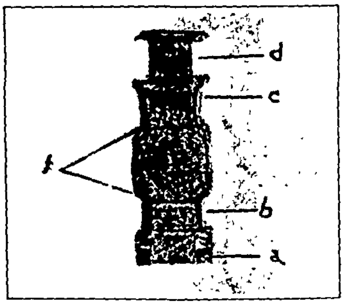

Fig. 2.—Clamp model 2; a, hinge; b, groove for elastic band; c, groove for elastic band; d, groove for catgut; f, space for artery.

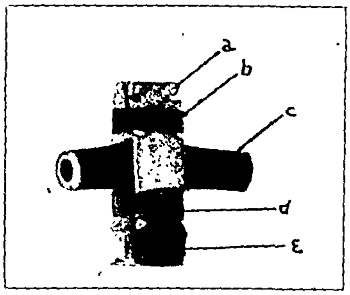

Fig. 3.—Clamp model 2; a, hinge; b, rubber elastic; c, artery; d, rubber elastic; e, catgut wound around one blade.

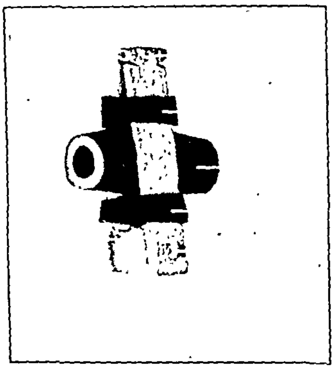

Fig. 4.—Clamp model 1; a, hinge; b, rubber band; c, artery; d, rubber band; e, pin through decalcified bone; f, decalcified bone.

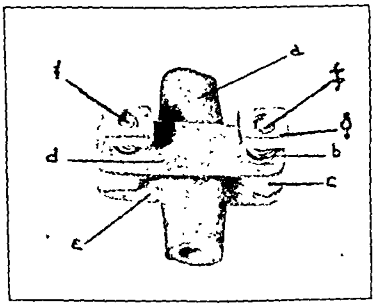

Fig. 5.—Clamp model 3; a, artery; b, spiral spring; c, decalcified bone; d and e, blades of clamp.

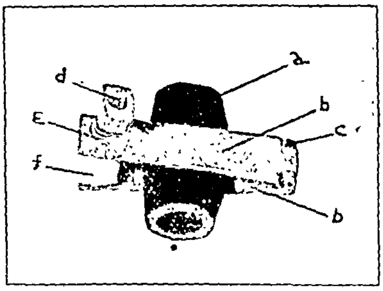

Fig. 6.—Clamp model 4; a, artery; b, blades of clamp; c, hinge; d, curve pin transfixing bone; e, spiral spring; f, decalcified bone.

When decalcified bone is used the underlying principle is exactly the same as with catgut; the bone is gradually absorbed and allows the blades to slowly come together.

Model 3 (illustrated in Figure 5) was used in only one experiment, so we have not had sufficient experience with it to draw conclusions as to its use. It consists of two separate blades (*d* and *e*), the opposing edges of which are rounded off to prevent cutting of the vessel. To the under blade (*e*) are fixed two upright threaded posts (*f*) which pass through two corresponding perforations in the upper blade (*d*). Two pieces of sterile decalcified bone (*c*) of proper thickness, are drilled and placed one on each of the upright posts (*f*) next to the blade (*e*). This blade is now put under the artery so that the latter occupies the position (*a*) shown in the illustration. The upper blade (*d*) is then placed in position and a small spiral spring (*b*) slipped over each of the upright posts (*f*). Now by screwing the nuts (*g*) into position, the upper blade (*d*) is pressed firmly against the decalcified bone (*c*), and as the latter is gradually absorbed, it will be slowly approximated to the blade (*e*). The disadvantages of this clamp are that it is complicated and occupies much more room than Model 2. Catgut can be used on each of the posts instead of decalcified bone.

Model 4 (shown in Figure 6) was used in only one case; it seems to possess no advantage over the simpler models, 1 and 2. A glance at the illustration will show that the working principle is the same, but instead of the rubber bands a spiral spring (*e*) is used to approximate the two blades. Magnesium, which is slowly absorbed by the tissues, can be used in the construction of the clamp instead of aluminum.

We have used the clamps in thirty-four experiments on dogs, twenty-seven times on the common carotids, five times on the aorta and twice on the femorals. Four of the aorta subjects died, one from general peritonitis, one from hemorrhage, one from double pyonephrosis, and one from secondary hemorrhage plus infection. Of the thirty remaining cases, complete occlusion was found at second operation in twenty-two, partial occlusion in seven and none at all in one.

Plain sterile catgut was used on one or both blades of the clamp in twelve cases and was completely absorbed after thirty and one-half days (average) in eleven cases. In the remaining case all of it was absorbed, except a very s[illegible]ween the blades. Iodin catgut, after [illegible] was used in fifteen cases and was found completely absorbed after twenty-eight days (average) in only three. Of the remaining twelve cases, it was in various stages of partial absorption in eleven, and showed no evidences of absorption in one.

Of the fourteen cases of complete absorption there was only one in which the vessel was not entirely occluded, the cause of failure in this one being too great separation of the blades by the set-screw.

In the cases in which the iodin catgut was only partly absorbed, it had been in the tissues, on an average, thirty-three days for each experiment.

Decalcified bone was used in three of the thirty experiments. In two cases it was completely absorbed after thirty-five days and in one, only a small fragment remained after twenty-four days. In only one of the thirty cases was there secondary hemorrhage and that was due to injury

REPORT OF EXPERIMENTS

Experiment 1.—Dog 12. Yellow male, weight 42 pounds. Operation, March 22, 1911. Right common carotid ligated.

Clamp Model 1, with plain No. 2 catgut on both blades applied to left common carotid. Second operation, April 20, 1911. Primary union of wound. Clamp found free in connective tissue capsule. Catgut entirely absorbed and blades together. Section of artery removed and split longitudinally from both ends (Fig. 7). Artery completely occluded and ends (*g*) united by fibrous tissue (*d*). A small clot (*c* and *e*) present in each occluded end.

EXPERIMENT 2.—Dog 13. Brindle bull, weight 50 pounds. Operation, March 24, 1911. Clamp Model 1, with plain No. 2 common carotid. Second operation, April 22, 1911. Catgut on outside of clamp entirely absorbed, but enough left between blades to prevent complete occlusion of artery. Clamp removed, fresh catgut wound around one of the blades, and reapplied to proximal portion of artery. Third operation, May 26, 1911. Catgut completely absorbed, and blades together. When the clamp was removed, weak pulsation was felt in distal segment. Section of artery removed and examined (Fig. 9). Portion of artery in grasp of clamp (*c*) greatly narrowed almost to the point of obliteration. No intravascular clots.

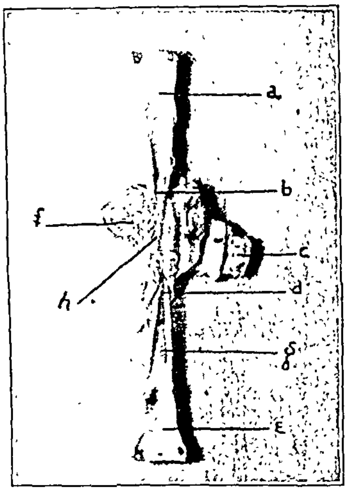

Fig. 13.—Dog 19; right common carotid. Exp. 10; a, below occlusion; b and d, occluded ends of artery; c, clamp in position; e, above occlusion; f, fibrous capsule around clamp; g, clot; h, fibrous tissue between ends.

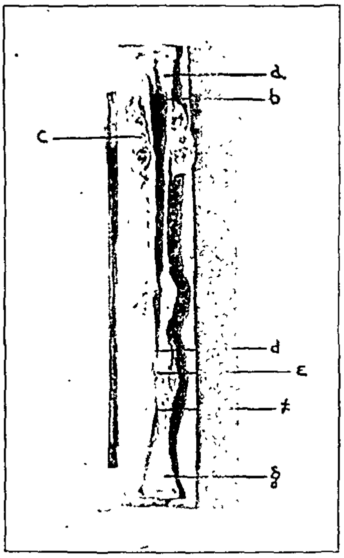

Fig. 14.—Dog 19; left common carotid. Exp. 11; a, above occlusion; b, clot; c, site of previous compression; d, occluded end of artery; e, fibrous tissue between ends; f, occluded end; g, below occlusion.

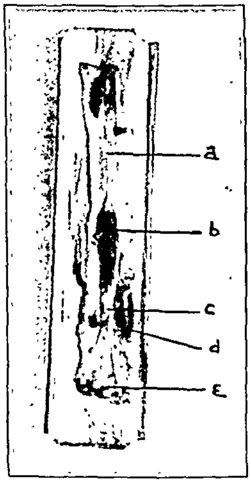

Fig. 17.—Dog 21; left common carotid. Exp. 15; a, below occlusion; b, clot; c, site of occlusion; d, part of fibrous capsule around clamp; e, above occlusion.

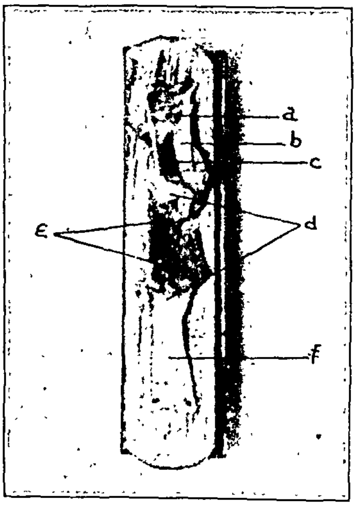

Fig. 18.—Dog 23; right common carotid. Exp. 18; a, collateral; b, above occlusion; c, clot; d, occluded ends of artery; e, fibrous tissue between ends; f, below occlusion.

catgut on one blade applied to right common carotid. Second operation, April 22, 1911. Primary union of wound. Clamp embedded in fibrous capsule. Catgut entirely absorbed and blades together. Section of artery removed and examined (Fig. 8). It was completely occluded at site of compression (*d*) and ends were united by dense fibrous tissue. A small clot (*c* and *e*) filled each of the occluded ends.

EXPERIMENT 3.—Dog 13. Operation, March 24, 1911. Model 1 clamp with plain No. 2 catgut on one blade applied to left

EXPERIMENT 4.—Dog 14. Small puppy. Operation, March 25, 1911. Clamp Model 1, with plain catgut on both blades applied to abdominal aorta below origin of renal arteries. Thoracic duct injured during the application. Dog died March 27 of general peritonitis. No changes found in aorta.

EXPERIMENT 5.—Dog 15. White male, weight 28 pounds. Operation, March 28, 1911. Clamp Model 1 with decalcified bone separating blades applied to abdominal aorta. Dog developed a paraplegia, April 5, and died April 8. Necropsy

showed general peritonitis, and hemorrhage from a perforation of the aorta beneath the clamp.

Experiment 6.—Dog 16. Female bird dog, weight 40 pounds. Operation, April 3, 1911. Clamp Model 1, with decalcified bone separating blades applied to abdominal aorta. Second operation, May 18, 1911. Primary union of wound. Pulsation in femorals had been absent for three weeks. Aorta exposed, clamp imbedded in fibrous capsule (*c*, Fig. 10), decalcified bone *completely* absorbed and blades together. Section of aorta removed and examined (Figs. 10 and 11). Artery completely occluded at site of compression (*d*, Figs. 10 and 11) and portion of artery between the blades represented by a thin fibrous ribbon (*d*, Fig. 11). No intravascular clots. The vessel was closed on each side of clamp by fibrous union of its walls. The collaterals on both sides of the occlusion were large and numerous (*b*, Figs. 10 and 11).

Experiment 7.—Dog 17. Small white female. Weight 28 pounds. Operation, April 6, 1911. Clamp Model 3, with two pieces of decalcified bone separating blades, applied to abdominal aorta. Dog died April 16, 1911. Necropsy showed double pyonephrosis, with almost complete destruction of left kidney. Artery unchanged.

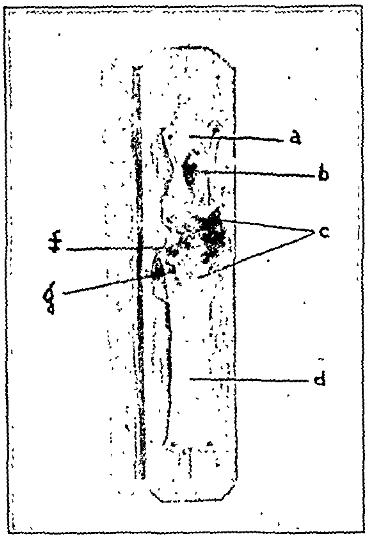

Fig. 19.—Dog 23; left common carotid. Exp. 19; a, above occlusion; b, clot; c, occluded ends of artery; d, below occlusion; f, fibrous tissue between ends of artery; g, point of perforation.

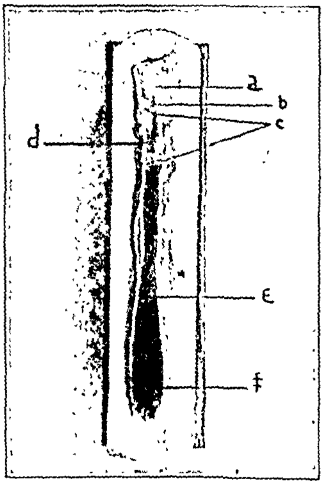

Fig. 20.—Dog 24; right common carotid. Exp. 20; a, above occlusion b, collateral; c, occluded ends of artery; d, fibrous tissue between occluded ends; e, clot; f, below occlusion.

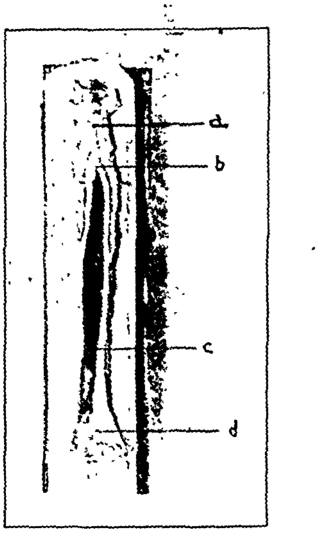

Fig. 21.—Dog 24; left common carotid. Exp. 21; a, fibrous tissue between occluded ends; b, occluded end of artery; c, clot d, artery below occlusion.

Experiment 8.—Dog 18. Small black female, weight 24 pounds. Operation, April 8, 1911. Clamp Model 4, with decalcified bone separating blades, applied to right common carotid. Second operation, May 2. Primary union of wound. Clamp in fibrous capsule. Nearly all of the bone was absorbed but a small amount remained between the blades. Very weak pulsation could be felt in artery distal to clamp.

Experiment 9.—Dog 18. Operation, April 8. Clamp Model 1 with decalcified bone separating blades applied to left common carotid. Second operation, May 2. Primary union of wound. Clamp embedded in fibrous capsule, bone completely absorbed and blades *together*. *Section of artery removed and* examined (Fig. 12). Artery is perfectly occluded at site of compression and each end tapers to a point (*b* and *d*). Ends united by fibrous tissue (*c*). No intravascular clots.

Experiment 10.—Dog 19. White bull terrier. Weight 32 pounds. Operation, April 13, 1911. Clamp Model 1, with plain No. 1 catgut on both blades applied to right common carotid. Second operation, May 5. Primary union of wound. Clamp embedded in fibrous capsule. Catgut was partially absorbed from both blades but *not sufficiently to completely obliterate* artery. Clamp removed and reapplied with fresh catgut, No. 1 plain, to proximal portion of artery. Third operation, June 2. Small superficial sinus at upper angle of wound not communicating with clamp. Clamp imbedded in fibrous capsule (Fig. 13, *f*). Catgut completely absorbed and blades together. No pulsation in distal segment. Section of artery removed and examined (Fig. 13). Vessel completely occluded at sight of compression, each end tapering to a point (*b* and *d*), small clot (*g*) in distal segment. Ends united by fibrous tissue (*h*).

Experiment 11.—Dog 19. Operation, April 13, 1911. Clamp Model 1 with plain No. 1 catgut on both blades applied to left common carotid. Second operation, May 5. Clamp in fibrous capsule. Catgut partially absorbed from both blades but not sufficiently to obliterate pulsation. Clamp removed and reapplied with fresh plain catgut to proximal portion of artery. Third operation, June 2. Clamp in fibrous capsule, catgut completely absorbed and blades together. Section of artery removed and examined (Fig. 14). Artery perfectly occluded at site of compression, and each end tapers to a point (*d* and *f*). Ends united by fibrous tissue (*c*). Distal segment contains an organizing blood-clot (*b*) extending from point of occlusion (*d*), *to point of previous application of clamp* (*c*).

Experiment 12.—Dog 20. White female bull. Weight 28 pounds. Operation, April 14, 1911. Clamp Model 1, with No. 1 iodin catgut on both blades applied to right common carotid. Second operation, May 6. Clamp in fibrous capsule and catgut partly absorbed. Weak pulsation distal *to* clamp. Clamp removed and one of Model 2 with No. 0 iodin catgut on one blade applied to proximal portion of artery. Third operation. June 3. Primary union. Clamp in fibrous capsule (*c*, Fig. 15). Catgut entirely absorbed and blades together. Section of artery removed and examined (Fig. 15). Artery completely occluded at site of compression *and each end tapers to a point* (*b* and *e*). Distal segment contains a small organized blood-clot. Ends united by fibrous tissue.

Experiment 13.—Dog 20. Operation, April 14, 1911. Clamp Model 1, with No. 1 iodin catgut on both blades, applied to left common carotid. Second operation, May 6, clamp in fibrous capsule and catgut partly absorbed from both blades. Section of artery removed and examined (Fig. 16). The artery between the blades was not obliterated but instead was considerably dilated when the pressure was removed (*c*, Fig. 16). With the clamp in place the vessel was occluded by approximation of the walls, but when removed it expanded like a fusiform aneurysm. A small clot filling the lumen of the vessel was loosely attached at the site of compression.

Experiment 14.—Dog 21. Female brindle bull. Weight 46 pounds. Operation, April 23, 1911. Clamp Model 2 with No. 0 iodin catgut on both blades applied to right common carotid artery. Second operation, May 26. Pulsation present distal to compression, so clamp was left in place. Third operation.

June 9. Clamp in fibrous capsule, pulsation in distal segment almost as strong as in proximal. Practically no absorption of catgut. The iodin catgut was removed from the clamp and one blade wound with No. 2 plain gut.

EXPERIMENT 15.—Dog 21. Operation, April 23. Clamp Model 2, with No. 0 iodin catgut on both blades applied to left common carotid artery. Second operation, May 26. Clamp in fibrous capsule, catgut partially absorbed and blades almost together. No pulsation distal to clamp. Section removed and examined (Fig. 17). The portion of artery in the grasp of the clamp (c) greatly narrowed, and obliteration of the lumen in progress. In distal segment there is an organizing clot (b) filling the lumen.

EXPERIMENT 16.—Dog 22. Black and tan male. Weight 18 pounds. Operation, April 24, 1911. Clamp Model 2, with No. 0 iodin catgut on one blade applied to right common carotid. Second operation, May 29. Pulsation present distal to clamp. Catgut partly absorbed but not sufficiently to occlude artery. Clamp left in place. *Third operation, June 14. Clamp in* fibrous capsule. Catgut almost entirely absorbed but just sufficient of it left between blades to prevent obliteration of artery. Very feeble pulsation distal to clamp. Section of artery removed and examined. Artery was practically occluded by approximation of its walls in grasp of clamp. On longitudinal section, however, it exhibited practically no change except a darkening of the intima at site of compression.

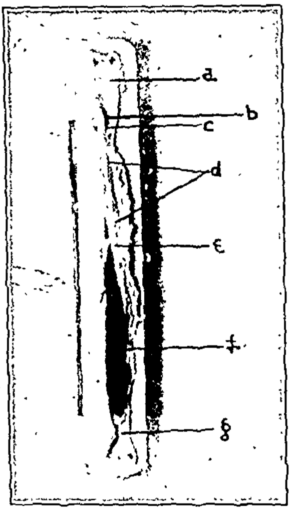

Fig. 22.—Dog 25; right common carotid. Exp. 22; a, above occlusion; b, collateral; c and e, occluded ends of artery; f, clot; g, below occlusion; d, fibrous tissue between ends.

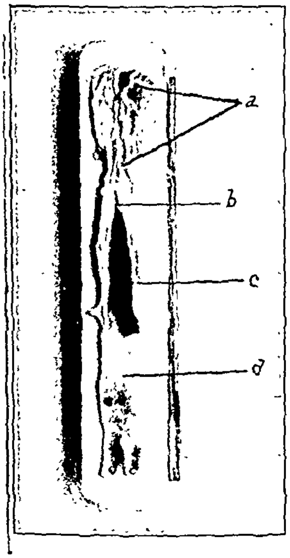

Fig. 23.—Dog 25; left common carotid. Exp. 23; a, fibrous tissue between occluded ends of artery; b, occluded proximal end; c, clot; d, artery below occlusion.

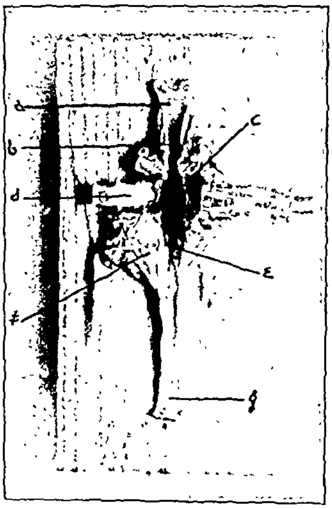

Fig. 24.—Dog 27; right common carotid. Exp. 26; a, above occlusion; b, clot; c, portion of artery in clamp; d, clamp in position; e, clot; f, fibrous capsule around clamp; g, below occlusion.

EXPERIMENT 17.—Dog 22. Operation, April 24, 1911. Clamp Model 2, with No. 0 iodin catgut on one blade applied to left common carotid. Second operation, May 29. Catgut partly absorbed but not sufficiently to stop pulsation. Clamp left in place. Third operation, June 14. Primary union of wound. Clamp in fibrous capsule. Catgut almost completely absorbed but enough left between blades to prevent obliteration of artery. Feeble pulsation distal to clamp. Section of artery removed and examined. Same description applies here as to specimen removed from experiment 16.

EXPERIMENT 18.—Dog 23. Female bird dog. Weight 40 pounds. Operation, April 27, 1911. Clamp Model 2, with No. 0 iodin catgut on both blades applied to right common carotid. Second operation, May 18. Primary union of wound. Clamp in fibrous capsule. All of the catgut had been absorbed from one blade and most of it from the other, allowing the blades to come together. Section removed and examined (Fig. 18). The artery was completely occluded at site of compression, and the ends (d) closed by organic union. Ends united by fibrous tissue (c). Small clot (c) in distal end.

EXPERIMENT 19.—Dog 23. Operation, April 27, 1911. Clamp Model 2, with No. 0 iodin catgut on both blades applied to left common carotid artery. Second operation, May 18. Hematoma, the size of a small orange, present in neck beneath scar. Three days before operation, dog was kicked in neck during a fight, which accounted for the hemorrhage. Left common carotid exposed. Clamp found free from artery. About half of catgut had been absorbed from both blades, permitting them to come close together. Section of artery removed and examined (Fig. 19). Artery was perfectly occluded at site of compression (*f*). Distal end containing a small clot (*b*) was occluded by a fibrous union of its walls (*c*). Proximal end too was occluded by organic union (*c*); except at one point (*g*) in the line of union, from which hemorrhage had taken place. This rupture had evidently been caused by the impact of the clamp against the vessel end when the dog was kicked.

EXPERIMENT 20.—Dog 24. White puppy. Weight 25 pounds. Operation, April 27, 1911. Clamp Model 2, with No. 0 iodin *catgut on both blades applied to right common carotid.* Second operation, May 29. Primary union of wound. Clamp in fibrous capsule. Catgut on both blades was almost entirely absorbed and blades were together. Section removed and examined (Fig. 20). Artery completely occluded at site of compression (*d*) each occluded end tapering to a point (*c*). Ends united by fibrous tissue (*d*). In proximal segment is a clot (*c*) which fills the vessel.

EXPERIMENT 21.—Dog 24. Operation, April 27. Clamp Model 2 with No. 0 iodin catgut on both blades applied to left common carotid. Second operation, May 29. Primary union of wound. Clamp in fibrous capsule. All of the catgut on one blade was absorbed and all but one layer from the other. Blades were together. Section removed and examined (Fig. 21). Vessel was completely occluded at site of compression and proximal end tapered to a point (*b*). Beyond proximal end was firm fibrous tissue (*a*). A clot (*c*) completely filled this segment of the artery. The distal end was not included in the excised portion.

EXPERIMENT 22.—Dog 25. Yellow male. Weight 45 pounds. Operation, May 3, 1911. Clamp Model 2, with No. 0 iodin catgut, applied to right common carotid. Second operation, May 31. In lower portion of wound a sinus leads down to situation of clamp. Clamp free from artery, catgut entirely absorbed and blades together. No pulsation beyond clamp. Section removed and examined (Fig. 22). Artery completely occluded, each end tapering to a point, (*c and c*). The ends were united by *fibrous tissue* (*d*). In proximal segment a clot (*f*) completely fills the lumen.

showed general peritonitis, and hemorrhage from a perforation of the aorta beneath the clamp.

Experiment 6.—Dog 16. Female bird dog, weight 40 pounds. Operation, April 3, 1911. Clamp Model 1, with decalcified bone separating blades applied to abdominal aorta. Second operation, May 18, 1911. Primary union of wound. Pulsation in femorals had been absent for three weeks. Aorta exposed, clamp imbedded in fibrous capsule (*c*, Fig. 10), decalcified bone completely absorbed and blades together. Section of aorta removed and examined (Figs. 10 and 11). Artery completely occluded at site of compression (*d*, Figs. 10 and 11) and portion of artery between the blades represented by a thin fibrous ribbon (*d*, Fig. 11). No intravascular clots. The vessel was closed on each side of clamp by fibrous union of its walls. The collaterals on both sides of the occlusion were large and numerous (*b*, Figs. 10 and 11).

Experiment 7.—Dog 17. Small white female. Weight 28 pounds. Operation, April 6, 1911. Clamp Model 3, with two pieces of decalcified bone separating blades, applied to abdominal aorta. Dog died April 16, 1911. Necropsy showed double pyonephrosis, with almost complete destruction of left kidney. Artery unchanged.

Experiment 8.—Dog 18. Small black female, weight 24 pounds. Operation, April 8, 1911. Clamp Model 4, with decalcified bone separating blades, applied to right common carotid. Second operation, May 2. Primary union of wound. Clamp in fibrous capsule. Nearly all of the bone was absorbed but a small amount remained between the blades. Very weak pulsation could be felt in artery distal to clamp.

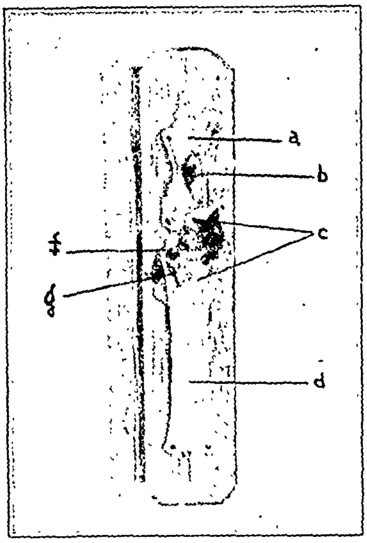

Fig. 19.—Dog 23; left common carotid. Exp. 19; a, above occlusion; b, clot; c, occluded ends of artery; d, below occlusion; f, fibrous tissue between ends of artery; g, point of perforation.

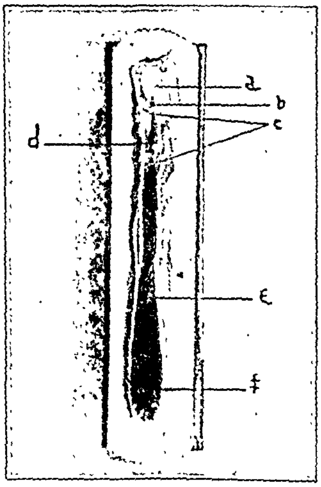

Fig. 20.—Dog 24; right common carotid. Exp. 20; a, above occlusion, b, collateral; c, occluded ends of artery; d, fibrous tissue between occluded ends; e, clot; f, below occlusion.

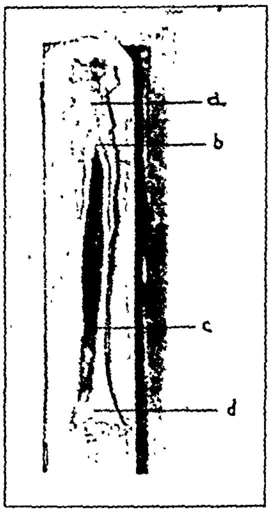

Fig. 21.—Dog 24; left common carotid. Exp. 21; a, fibrous tissue between occluded ends; b, occluded end of artery; c, clot; d, artery below occlusion.

Experiment 9.—Dog 18. Operation, April 8. Clamp Model 1 with decalcified bone separating blades applied to left common carotid. Second operation, May 2. Primary union of wound. Clamp embedded in fibrous capsule, bone completely absorbed and blades together. Section of artery removed and examined (Fig. 12). Artery is perfectly occluded at site of compression and each end tapers to a point (*b* and *d*). Ends united by fibrous tissue (*c*). No intravascular clots.

Experiment 10.—Dog 19. White bull terrier. Weight 32 pounds. Operation, April 13, 1911. Clamp Model 1, with plain No. 1 catgut on both blades applied to right common carotid. Second operation, May 5. Primary union of wound. Clamp embedded in fibrous capsule. Catgut was partially absorbed from both blades but not sufficiently to completely obliterate artery. Clamp removed and reapplied with fresh catgut, No. 1 plain, to proximal portion of artery. Third operation, June 2. Small superficial sinus at upper angle of wound not communicating with clamp. Clamp imbedded in fibrous capsule (Fig. 13, *f*). Catgut completely absorbed and blades together. No pulsation in distal segment. Section of artery removed and examined (Fig. 13). Vessel completely occluded at sight of compression, each end tapering to a point (*b* and *d*), small clot (*g*) in distal segment. Ends united by fibrous tissue (*h*).

Experiment 11.—Dog 19. Operation, April 13, 1911. Clamp Model 1 with plain No. 1 catgut on both blades applied to left common carotid. Second operation, May 5. Clamp in fibrous capsule. Catgut partially absorbed from both blades but not sufficiently to obliterate pulsation. Clamp removed and reapplied with fresh plain catgut to proximal portion of artery. Third operation, June 2. Clamp in fibrous capsule, catgut completely absorbed and blades together. Section of artery removed and examined (Fig. 14). Artery perfectly occluded at site of compression, and each end tapers to a point (*d* and *f*). Ends united by fibrous tissue (*e*). Distal segment contains an organizing blood-clot (*b*) extending from point of occlusion (*d*), to point of previous application of clamp (*c*).

Experiment 12.—Dog 20. White female bull. Weight 28 pounds. Operation, April 14, 1911. Clamp Model 1, with No. 1 iodin catgut on both blades applied to right common carotid. Second operation, May 6. Clamp in fibrous capsule and catgut partly absorbed. Weak pulsation distal to clamp. Clamp removed and one of Model 2 with No. 0 iodin catgut on one blade applied to proximal portion of artery. Third operation. June 3. Primary union. Clamp in fibrous capsule (*c*, Fig. 15). Catgut entirely absorbed and blades together. Section of artery removed and examined (Fig. 15). Artery completely occluded at site of compression and each end tapers to a point (*b* and *e*). Distal segment contains a small organized blood-clot. Ends united by fibrous tissue.

Experiment 13.—Dog 20. Operation, April 14, 1911. Clamp Model 1, with No. 1 iodin catgut on both blades, applied to left common carotid. Second operation, May 6, clamp in fibrous capsule and catgut partly absorbed from both blades. Section of artery removed and examined (Fig. 16). The artery between the blades was not obliterated but instead was considerably dilated when the pressure was removed (*c*, Fig. 16). With the clamp in place the vessel was occluded by approximation of the walls, but when removed it expanded like a fusiform aneurysm. A small clot filling the lumen of the vessel was loosely attached at the site of compression.

Experiment 14.—Dog 21. Female brindle bull. Weight 46 pounds. Operation, April 23, 1911. Clamp Model 2 with No. 0 iodin catgut on both blades applied to right common carotid artery. Second operation, May 26. Pulsation present distal to compression, so clamp was left in place. Third operation,

showed general peritonitis, and hemorrhage from a perforation of the aorta beneath the clamp.

EXPERIMENT 6.—Dog 16. Female bird dog, weight 40 pounds. Operation, April 3, 1911. Clamp Model 1, with decalcified bone separating blades applied to abdominal aorta. Second operation, May 18, 1911. Primary union of wound. Pulsation in femorals had been absent for three weeks. Aorta exposed, clamp imbedded in fibrous capsule (*c*, Fig. 10), decalcified bone completely absorbed and blades together. Section of aorta removed and examined (Figs. 10 and 11). Artery completely occluded at site of compression (*d*, Figs. 10 and 11) and portion of artery between the blades represented by a thin fibrous ribbon (*d*, Fig. 11). No intravascular clots. The vessel was closed on each side of clamp by fibrous union of its walls. The collaterals on both sides of the occlusion were large and numerous (*b*, Figs. 10 and 11).

EXPERIMENT 7.—Dog 17. Small white female. Weight 28 pounds. Operation, April 6, 1911. Clamp Model 3, with two pieces of decalcified bone separating blades, applied to abdominal aorta. Dog died April 16, 1911. Necropsy showed double pyonephrosis, with almost complete destruction of left kidney. Artery unchanged.

EXPERIMENT 8.—Dog 18. Small black female, weight 24 pounds. Operation, April 8, 1911. Clamp Model 4, with decalcified bone separating blades, applied to right common carotid. Second operation, May 2. Primary union of wound. Clamp in fibrous capsule. Nearly all of the bone was absorbed but a small amount remained between the blades. Very weak pulsation could be felt in artery distal to clamp.

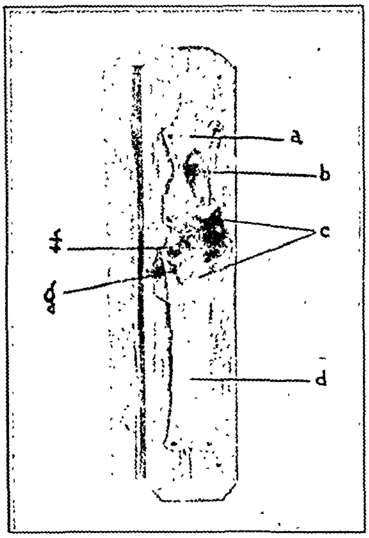

Fig. 19.—Dog 23; left common carotid. Exp. 19; a, above occlusion; b, clot; c, occluded ends of artery; d, below occlusion; f, fibrous tissue between ends of artery; g, point of perforation.

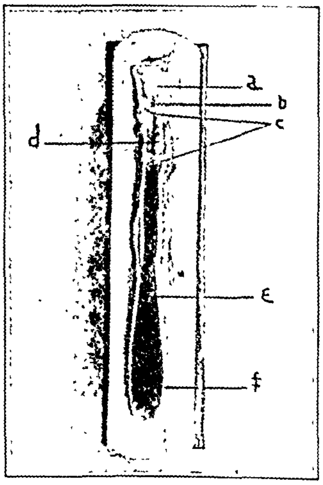

Fig. 20.—Dog 24; right common carotid. Exp. 20; a, above occlusion, b, collateral; c, occluded ends of artery; d, fibrous tissue between occluded ends; e, clot; f, below occlusion.

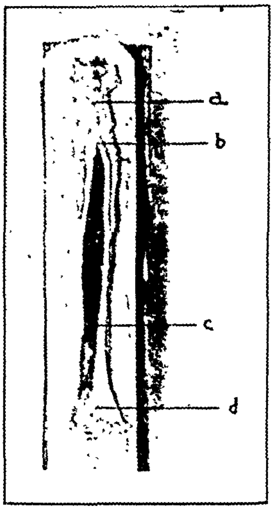

Fig. 21.—Dog 24; left common carotid. Exp. 21; a, fibrous tissue between occluded ends; b, occluded end of artery; c, clot; d, artery below occlusion.

EXPERIMENT 9.—Dog 18. Operation, April 8. Clamp Model 1 with decalcified bone separating blades applied to left common carotid. Second operation, May 2. Primary union of wound. Clamp embedded in fibrous capsule, bone completely absorbed and blades together. Section of artery removed and examined (Fig. 12). Artery is perfectly occluded at site of compression and each end tapers to a point (*b* and *d*). Ends united by fibrous tissue (*c*). No intravascular clots.

EXPERIMENT 10.—Dog 19. White bull terrier. Weight 32 pounds. Operation, April 13, 1911. Clamp Model 1, with plain No. 1 catgut on both blades applied to right common carotid. Second operation, May 5. Primary union of wound. Clamp embedded in fibrous capsule. Catgut was partially absorbed from both blades but not sufficiently to completely obliterate artery. Clamp removed and reapplied with fresh catgut, No. 1 plain, to proximal portion of artery. Third operation, June 2. Small superficial sinus at upper angle of wound not communicating with clamp. Clamp imbedded in fibrous capsule (Fig. 13, *f*). Catgut completely absorbed and blades together. No pulsation in distal segment. Section of artery removed and examined (Fig. 13). Vessel completely occluded at sight of compression, each end tapering to a point (*b* and *d*), small clot (*a*) in distal segment. Ends united by fibrous tissue (*h*).

EXPERIMENT 11.—Dog 19. Operation, April 13, 1911. Clamp Model 1 with plain No. 1 catgut on both blades applied to left common carotid. Second operation, May 5. Clamp in fibrous capsule. Catgut partially absorbed from both blades but not sufficiently to obliterate pulsation. Clamp removed and reapplied with fresh plain catgut to proximal portion of artery. Third operation, June 2. Clamp in fibrous capsule, catgut completely absorbed and blades together. Section of artery removed and examined (Fig. 14). Artery perfectly occluded at site of compression, and each end tapers to a point (*d* and *f*). Ends united by fibrous tissue (*e*). Distal segment contains an organizing blood-clot (*b*) extending from point of occlusion (*d*), to point of previous application of clamp (*c*).

EXPERIMENT 12.—Dog 20. White female bull. Weight 28 pounds. Operation, April 14, 1911. Clamp Model 1, with No. 1 iodin catgut on both blades applied to right common carotid. Second operation, May 6. Clamp in fibrous capsule and catgut partly absorbed. Weak pulsation distal to clamp. Clamp removed and one of Model 2 with No. 0 iodin catgut on one blade applied to proximal portion of artery. Third operation, June 3. Primary union. Clamp in fibrous capsule (*c*, Fig. 15). Catgut entirely absorbed and blades together. Section of artery removed and examined (Fig. 15). Artery completely occluded at site of compression and each end tapers to a point (*b* and *e*). Distal segment contains a small organized blood-clot. Ends united by fibrous tissue.

EXPERIMENT 13.—Dog 20. Operation, April 14, 1911. Clamp Model 1, with No. 1 iodin catgut on both blades, applied to left common carotid. Second operation, May 6, clamp in fibrous capsule and catgut partly absorbed from both blades. Section of artery removed and examined (Fig. 16). The artery between the blades was not obliterated but instead was considerably dilated when the pressure was removed (*c*, Fig. 16). With the clamp in place the vessel was occluded by approximation of the walls, but when removed it expanded like a fusiform aneurysm. A small clot filling the lumen of the vessel was loosely attached at the site of compression.

EXPERIMENT 14.—Dog 21. Female brindle bull. Weight 46 pounds. Operation, April 23, 1911. Clamp Model 2 with No. 0 iodin catgut on both blades applied to right common carotid artery. Second operation, May 26. Pulsation present distal to compression, so clamp was left in place. Third operation, June 9. Clamp in fibrous capsule, pulsation in distal segment almost as strong as in proximal. Practically no absorption of catgut. The iodin catgut was removed from the clamp and one blade wound with No. 2 plain gut.

Experiment 15.—Dog 21. Operation, April 23. Clamp Model 2, with No. 0 iodin catgut on both blades applied to left common carotid artery. Second operation, May 26. Clamp in fibrous capsule, catgut partially absorbed and blades almost together. No pulsation distal to clamp. Section removed and examined (Fig. 17). The portion of artery in the grasp of the clamp (c) greatly narrowed, and obliteration of the lumen in progress. In distal segment there is an organizing clot (*b*) filling the lumen.

Experiment 16.—Dog 22. Black and tan male. Weight 18 pounds. Operation, April 21, 1911. Clamp Model 2, with No. 0 iodin catgut on one blade applied to right common carotid. Second operation, May 29. Pulsation present distal to clamp. Catgut partly absorbed but not sufficiently to occlude artery. Clamp left in place. Third operation, June 14. Clamp in fibrous capsule. Catgut almost entirely absorbed but just sufficient of it left between blades to prevent obliteration of artery. Very feeble pulsation distal to clamp. Section of artery removed and examined. Artery was practically occluded. by approximation of its walls in grasp of clamp. On longitudinal section, however, it exhibited practically no change except a darkening of the intima at site of compression.

Experiment 17.—Dog 22. Operation, April 24, 1911. Clamp Model 2, with No. 0 iodin catgut on one blade applied to left common carotid. Second operation, May 29. Catgut partly absorbed but not sufficiently to stop pulsation. Clamp left in place. Third operation, June 14. Primary union of wound. Clamp in fibrous capsule. Catgut almost completely absorbed but enough left between blades to prevent obliteration of artery. Feeble pulsation distal to clamp. Section of artery removed and examined. Same description applies here as to specimen removed from experiment 16.

Experiment 18.—Dog 23. Female bird dog. Weight 40 pounds. Operation, April 27, 1911. Clamp Model 2, with No. 0 iodin catgut on both blades applied to right common carotid. Second operation, May 18. Primary union of wound. Clamp in fibrous capsule. All of the catgut had been absorbed from one blade and most of it from the other, allowing the blades to come together. Section removed and examined (Fig. 18). The artery was completely occluded at site of compression, and the ends (*d*) closed by organic union. Ends united by fibrous tissue (*c*). Small clot (*c*) in distal end.

Experiment 19.—Dog 23. Operation, April 27, 1911. Clamp Model 2, with No. 0 iodin catgut on both blades applied to left common carotid artery. Second operation, May 18. Hematoma, the size of a small orange, present in neck beneath scar. Three days before operation, dog was kicked in neck during a fight, which accounted for the hemorrhage. Left common carotid exposed. Clamp found free from artery. About half of catgut had been absorbed from both blades, permitting them to come close together. Section of artery removed and examined (Fig. 19). Artery was perfectly occluded at site of compression (*f*). Distal end containing a small clot (*b*) was occluded by a fibrous union of its walls (*c*). Proximal end too was occluded by organic union (*c*); except at one point (*a*) in the line of union, from which hemorrhage had taken place. This rupture had evidently been caused by the impact of the clamp against the vessel end when the dog was kicked.

Experiment 20.—Dog 24. White puppy. Weight 25 pounds. Operation, April 27, 1911. Clamp Model 2, with No. 0 iodin catgut on both blades applied to right common carotid. Second operation, May 29. Primary union of wound. Clamp in fibrous capsule. Catgut on both blades was almost entirely absorbed and blades were together. Section removed and examined (Fig. 20). Artery completely occluded at site of compression (*d*) each occluded end tapering to a point (*c*). Ends united by fibrous tissue (*d*). In proximal segment is a clot (*c*) which fills the vessel.

Experiment 21.—Dog 24. Operation, April 27. Clamp Model 2 with No. 0 iodin catgut on both blades applied to left common carotid. Second operation, May 29. Primary union of wound. Clamp in fibrous capsule. All of the catgut on one blade was absorbed and all but one layer from the other. Blades were together. Section removed and examined (Fig. 21). Vessel was completely occluded at site of compression and proximal end tapered to a point (*b*). Beyond proximal end was firm fibrous tissue (*a*). A clot (*c*) completely filled this segment of the artery. The distal end was not included in the excised portion.

Experiment 22.—Dog 25. Yellow male. Weight 45 pounds. Operation, May 3, 1911. Clamp Model 2, with No. 0 iodin catgut, applied to right common carotid. Second operation, May 31. In lower portion of wound a sinus leads down to site of clamp. Clamp free from artery, catgut entirely absorbed and blades together. No pulsation beyond clamp. Section removed and examined (Fig. 22). Artery completely occluded, each end tapering to a point, (*c* and *e*). The ends were united by fibrous tissue (*d*). In proximal segment a clot (*f*) completely fills the lumen.

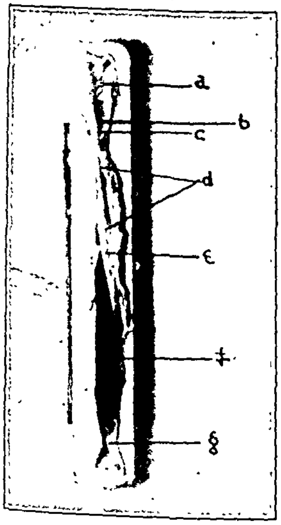

Fig. 22.—Dog 25; right common carotid. Exp. 22; a, above occlusion; b, collateral; c and e, occluded ends of artery; f, clot; g, below occlusion; d, fibrous tissue between ends.

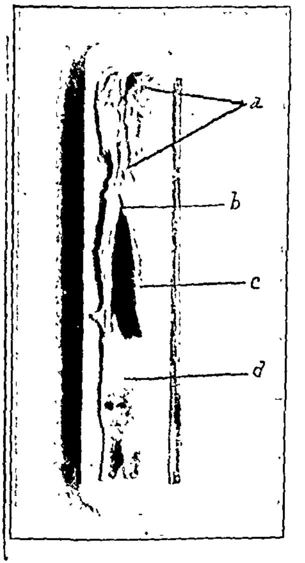

Fig. 23.—Dog 25; left common carotid. Exp. 23; a, fibrous tissue between occluded ends of artery; b, occluded proximal end; c, clot; d, artery below occlusion.

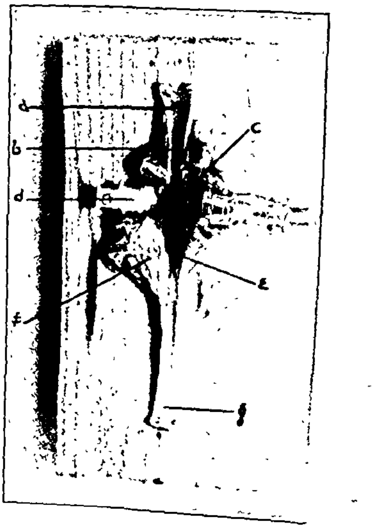

Fig. 24.—Dog 27; right common carotid. Exp. 26; a, above occlusion; b, distal portion of artery in clamp; d, clamp in position; e, clot; f, fibrous capsule around clamp; g, below occlusion.

Experiment 23.—Dog 25. Operation, May 3, 1911. Clamp Model 2, with No. 0 iodin catgut on one blade, applied to left common carotid. Second operation, May 31. Primary union of wound. Clamp in fibrous capsule and blades together. The catgut was entirely absorbed. Specimen removed and examined (Fig. 23). Vessel completely occluded and proximal segment tapered to a point (*b*). In this portion of the artery was a clot (*c*) which completely filled the lumen. Beyond the occluded end is dense fibrous tissue (*a*). The distal segment is not included in the specimen.

Experiment 24.—Dog 26. Black female, weight 24 pounds. Operation, May 5, 1911. Clamp Model 2, with No. 0 iodin catgut on both blades applied to right common carotid. Second operation, June 2. Weak pulsation felt distal to clamp. Catgut on blades partly absorbed but not sufficiently to occlude lumen. Clamp left in place. Third operation, June 15. Primary union. Clamp in fibrous capsule. Catgut absorbed excepting one layer which was enough to prevent complete occlusion of artery. Feeble pulsation distal to clamp. Clamp left in place.

Experiment 25.—Dog 26. Operation, May 5, 1911. Clamp Model 2, with No. 1 plain catgut on both blades applied to left common carotid. Second operation, June 2. Same description of second operation applies here as in Experiment 24. Third operation, June 15. Primary union. Clamp in fibrous capsule, all of the catgut absorbed and blades as close together as set screw would permit. Feeble pulsation distal to clamp. Section removed and examined. The portion of artery in the grasp of the clamp greatly thinned from pressure atrophy but showing no evidence of obliteration. In this case the set-screw did not permit blades to come together, and pressure atrophy so thinned the vessel wall that the circulation was permitted to go on through the clamp.

Experiment 26.—Dog 27. Brown male. Weight 36 pounds. Operation, May 6, 1911. Clamp Model 2 with No. 0 iodin catgut on one blade applied to right common carotid. Second operation, June 3. Primary union of wound. Very feeble pulsation distal to compression. Clamp in fibrous capsule (*f*, Fig. 24). Catgut partly absorbed but not sufficiently to allow blades to come together. Section removed and examined (Fig. 24). Portion of artery in grasp of clamp was greatly thinned (*c*) and showed evidence of obliterative endarteritis. There is a small clot (*b* and *c*) on each side of the clamp.

Experiment 27.—Dog 27. Operation, May 6, 1911. Clamp Model 2, with No. 0 iodin catgut on one blade applied to left common carotid. Second operation, June 3. Primary union of wound. Clamp in fibrous capsule (*c*, Fig. 25). Catgut partially absorbed but blades not together. Section of artery removed and examined (Fig. 25). Portion of artery in grasp of clamp (*f*) greatly thinned and narrowed and an obliterative endarteritis in progress. A small clot (*c* and *g*) present on each side of clamp.

Experiment 28.—Dog 28. Yellow male, weight 42 pounds. Operation, May 8, 1911. Clamp Model 2, with plain No. 1 catgut on one blade applied to right femoral artery. Second operation, June 8. There was a small sinus in scar which led down to clamp. Clamp was free from artery, catgut all absorbed and blades together. Artery completely divided and stumps separated one inch. Both stumps pulsated. Proximal and distal segments removed and examined (Fig. 26). Each segment tapered to a point (*c*) beyond which was dense fibrous tissue (*d*). No clot in either segment.

Experiment 29.—Dog 28. Operation, May 8. Clamp Model 2 with No. 1 plain catgut on one blade applied to left femoral artery. Second operation, June 8. Primary union of wound. Clamp was free from artery. Catgut entirely absorbed and blades together. The artery was completely divided and stumps separated 1 inch. Both stumps pulsated. Proximal and distal segments removed and examined (Fig. 27). Each segment tapered to a point (*c*) beyond which was fibrous tissue (*f*). Proximal segment contained a small clot (*d*) in the occluded end.

Experiment 30.—Dog 29. Small black female, weight 24 pounds. Operation, May 9, 1911. Clamp Model 2 with plain No. 1 catgut on both blades applied to abdominal aorta. Dog *died* May 15. For two days before death there was evidence of paraplegia. Post-mortem showed primary union of wound. Profuse hemorrhage in peritoneum and retroperitoneal space. Clamp in position. Catgut had begun to absorb. Section of aorta removed and examined. In anterior wall of artery was a small perforation which had evidently been caused by the pressure of the edge of the clamp. A small intravascular clot covered the perforation.

Experiment 31.—Dog 30. Black male. Weight 38 pounds. Operation, May 10, 1911. Clamp Model 2 with plain No. 1 catgut on one blade applied to right common carotid. Second operation, June 7. Primary union of wound. Clamp in fibrous capsule (*c*, Fig. 28), catgut entirely absorbed and blades together. No pulsation distal to clamp. Section of artery removed and examined (Fig. 28). Artery was perfectly occluded, each segment tapering to a point (*c*). Ends joined

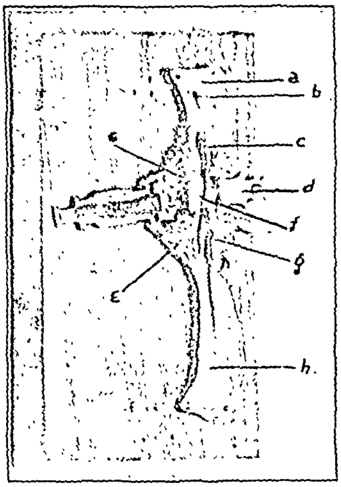

Fig. 25.—Dog 27; left common carotid. Exp. 27; a, above occlusion; b, collateral; c, clot; d, clamp in position; e, capsule around clamp; f, portion of artery in clamp; g, clot; h, below occlusion.

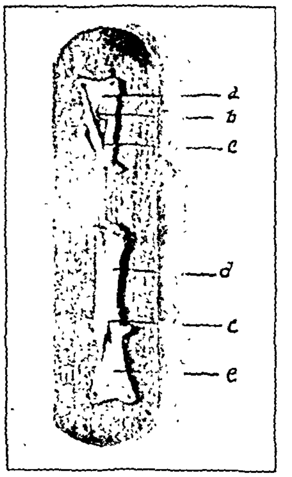

Fig. 26.—Dog 28; right femoral. Exp. 28; a, above occlusion; b, collateral; c, occluded ends of artery; d, fibrous tissue; e, below occlusion.

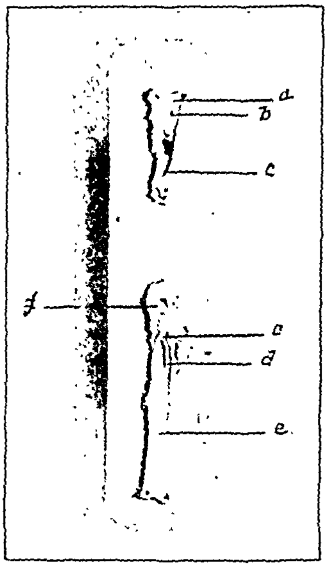

Fig. 27.—Dog 28; left femoral. Exp. 29; a, above occlusion; b, collateral; c, occluded ends of artery; d, small clot; e, below occlusion; f, fibrous tissue.

TABLE SHOWING RESULTS OF EXPERIMENTS

Exp. No.	Artery Clamped.	Type of Clamp.	Absorbable Material Used.	Time.	Degree of Occlusion Found at Second Operation.	Absorption of Catgut or Decalcified Bone.	Healing of Wound.	Symptoms After Application of Clamp.
1	Left common carotid	Model 1	Plain catgut	29 days	Complete	Completely absorbed	Primary union	None.
2	Right common carotid	Model 1	Plain catgut	29 days	Complete	Completely absorbed	Primary union	None.
3	Left common carotid	Model 1	Plain catgut	34 days	Complete	Completely absorbed	Primary union	None.
4	Abdominal aorta	Model 1	Plain catgut	2 days	No change. Death		Suppuration	General peritonitis.
5	Abdominal aorta	Model 1	Decalcified bone	11 days	Artery eroded. Hemorrhage. Death.		Suppuration	Paraplegia for 3 days before death.
6	Abdominal aorta	Model 1	Decalcified bone	45 days	Completely occluded	Completely absorbed	Primary union	None.
7	Abdominal aorta	Model 3	Decalcified bone	10 days	No change. Death from pyonephrosis.		Suppuration	No paraplegia.
8	Right common carotid	Model 4	Decalcified bone	24 days	Partial occlusion	Almost complete	Primary union	None.
9	Left common carotid	Model 1	Decalcified bone	24 days	Completely occluded	Completely absorbed	Primary union	None.
10	Right common carotid	Model 1	Plain catgut	28 days	Completely occluded	Completely absorbed	Small superficial sinus not communicating with clamp.	None.
11	Left common carotid	Model 1	Plain catgut	28 days	Completely occluded	Completely absorbed	Same as Exp. 10. Primary union of deep tissues.	None.
12	Right common carotid	Model 2	Iodin catgut, No. 0	28 days	Completely occluded	Completely absorbed	Primary union	None.
13	Left common carotid	Model 1	Iodin catgut, No. 1	22 days	Completely occluded	Partially absorbed	Primary union	None.
14	Right common carotid	Model 2	Iodin catgut, No. 0	47 days	Not occluded	Not absorbed	Primary union	None.
15	Left common carotid	Model 2	Iodin catgut, No. 0	33 days	Completely occluded	Partially absorbed	Primary union	None.
16	Right common carotid	Model 2	Iodin catgut, No. 0	51 days	Partly occluded	Partly absorbed	Primary union	None.
17	Left common carotid	Model 2	Iodin catgut, No. 0	51 days	Partly occluded	Partly absorbed	Primary union	None.
18	Right common carotid	Model 2	Iodin catgut, No. 0	21 days	Completely occluded	All catgut on one blade absorbed and most of it on the other.	Primary union	None.
19	Left common carotid	Model 2	Iodin catgut	21 days	Completely occluded	About one-half of gut absorbed from both blades.	Primary union	None.
20	Right common carotid	Model 2	Iodin catgut, No. 0	32 days	Completely occluded	Most of catgut absorbed from both blades.	Primary union	None.
21	Left common carotid	Model 2	Iodin catgut, No. 0	32 days	Completely occluded	All from one blade absorbed and most of it from other.	Primary union	None.
22	Right common carotid	Model 2	Iodin catgut, No. 0	28 days	Completely occluded	Completely absorbed	Sinus from skin to clamp on right c. carotid.	None.
23	Left common carotid	Model 2	Iodin catgut, No. 0	28 days	Completely occluded	Completely absorbed	Primary union	None.
24	Right common carotid	Model 2	Iodin catgut, No. 0	41 days	Partly occluded	Partly absorbed	Primary union	None.
25	Left common carotid	Model 2	Plain catgut, No. 1	41 days	Partly occluded	Completely absorbed	Primary union	None.
26	Right common carotid	Model 2	Iodin catgut, No. 0	28 days	Partial occlusion. Feeble pulsation distal to clamp.	Partial absorption of catgut from both blades.	Primary union	None.
27	Left common carotid	Model 2	Iodin catgut, No. 0	28 days	Completely occluded	Partial absorption from both blades.	Primary union	None.
28	Right femoral	Model 2	Plain catgut, No. 1	31 days	Completely occluded	Completely absorbed	Sinus leading to clamp.	None.
29	Left femoral	Model 2	Plain catgut	31 days	Completely occluded	Completely absorbed	Primary union	None.
30	Aorta	Model 2	Plain catgut, No. 1	6 days	Artery perforated by edge of clamp. Hemorrhage. Death.	Absorption had just started.	Primary union	Paraplegia for 3 days before death.
31	Right common carotid	Model 2	Plain catgut, No. 1	28 days	Completely occluded	Completely absorbed	Primary union	None.
32	Left common carotid	Model 2	Plain catgut, No. 1	28 days	Completely occluded	Completely absorbed	Primary union	None.
33	Right common carotid	Model 2	Plain catgut, No. 1	28 days	Completely occluded	Completely absorbed	Primary union	None.
34	Left common carotid	Model 2	Plain catgut	28 days	Partially occluded. Feeble pulsation distal to clamp.	Almost complete absorption. Small amount of gut between blades.	Primary union	None.

by fibrous tissue (*d*). Both segments of artery contained blood-clots (*b*).

EXPERIMENT 32.—Dog 30. Operation, May 10. Clamp Model 2 with No. 1 plain catgut on one blade applied to left common carotid. Second operation, June 7. Primary union of wound. Clamp in fibrous capsule (*f*, Fig. 29), catgut entirely absorbed and blades together. No pulsation distal to compression. Section of artery removed and examined (Fig. 29). Artery perfectly occluded, each end tapering to a point (*b*). Ends united by fibrous tissue (*c*). Each segment contained a small blood-clot (*d*).

EXPERIMENT 33.—Dog 31. Female shepherd. Weight 26 pounds. Operation, May 10. Clamp Model 2 with plain No. 1 catgut on one blade applied to right common carotid. Second operation, June 7. Primary union of wound. Clamp in fibrous capsule, catgut entirely absorbed and blades as close together as set-screw would permit. No pulsation distal to compression. Section of artery removed and examined (Fig. 30). Portion of artery (*d*) in grasp of clamp was perfectly occluded by approximation of its walls. An obliterative endarteritis was in progress as shown by union of the walls on one side (*b*). There was no intravascular clot. This case demonstrates the purpose for which the set-screw was intended; viz., the complete occlusion of the vessel without its division by the clamp.

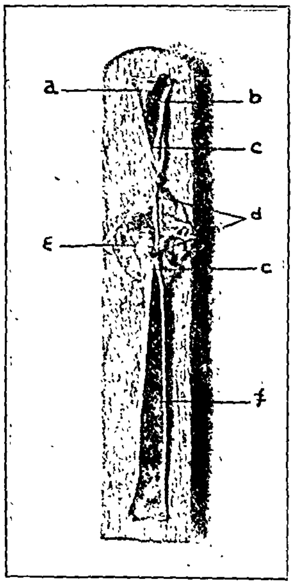

Fig. 28.—Dog 30; right common carotid. Exp. 31; a, above occlusion; b, clot; c, occluded ends of artery; d, fibrous tissue between ends; e, part of capsule around clamp; f, below occlusion.

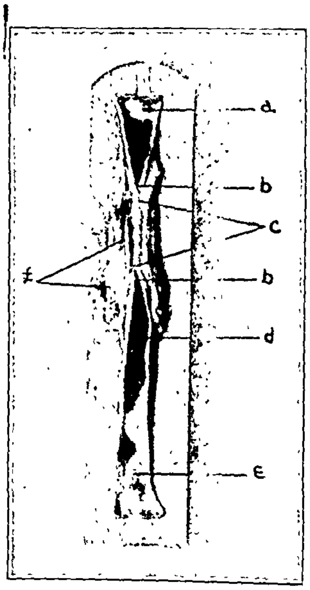

Fig. 29.—Dog 30; left common carotid. Exp. 32; a, above occlusion; b, occluded ends of artery; c, fibrous tissue between ends; d, clot; e, below occlusion; f, portion of fibrous capsule around clamp.

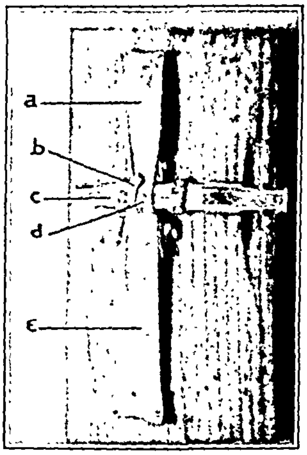

Fig. 30.—Dog 31; right common carotid. Exp. 33; a, above occlusion; b, portion of artery in clamp, where walls have united; c, clamp in position; d, portion of artery in clamp; e, below oclusion.

EXPERIMENT 34.—Dog 31. Operation, May 10. Clamp Model 2 with plain No. 1 catgut on one blade applied to left common carotid. Second operation, June 7. Primary union of wound. Clamp in fibrous capsule. All of the catgut on the outer surface was absorbed and only one layer left between the set-screw and the opposite blade. This prevented complete occlusion of the vessel. There was feeble pulsation distal to the compression. Artery not removed but one blade of clamp rewound with plain catgut and left in place.

CONCLUSIONS

1. Gradual automatic occlusion of the larger arteries at one operation can be uniformly produced by the method herein described.

2. Model 2, clamp with plain sterile catgut on one or both blades gives the best results. The absorption of iodin catgut is slow and uncertain.

3. The clamp with its elastic bands and catgut is perfectly tolerated by the tissues. The clamp becomes surrounded by a capsule of dense fibrous tissue, produces no irritation and may remain in place indefinitely.

4. The collateral circulation has an opportunity to develop during the process of gradual occlusion of the artery.

5. The ideal result is complete occlusion and division of the artery with tapering of the occluded ends and little or no clot formation.

6. The danger of secondary hemorrhage is slight: first, because the occlusion is gradually produced, and second, on account of the capsule of dense fibrous tissue which forms around the clamp and unites the two occluded ends of the vessel.

The accompanying table shows the results of our experiments.

I desire to thank Dr. M. M. Patton for very valuable services rendered in the work, also Drs. Jennings, Greenwald, Hamblen and the staff of the Washington State Veterinary College, Spokane, for their assistance.

306 Paulsen Bldg.

ABSTRACT OF DISCUSSION

DR. ROBERT C. COFFEY, Portland, Ore.: I was recently in Spokane and had Dr. Neff explain all his experiments to me, and I went over them carefully with him. It seems to me from his explanation and from what I have read and know of the previous devices for this same purpose, that Dr. Neff has put the climax on the subject of occlusion of arteries for the treatment of aneurysm. I believe he has solved the question of gradual occlusion which can be so regulated that a good collateral circulation may be established before complete occlusion takes place.

Baldness in Men and Women.—Degenerative changes in the blood-vessels and rigidity of the thorax, both characteristics of senility, are found much earlier in man than in woman. Man dies suddenly much oftener than woman. Men suffer from baldness more frequently than women. This is not confined to civilized races, but is found among savages and semi-civilized tribes, as in many of the North American Indians, even where it is the custom for the women, instead of the men to wear their hair short.—Stewart in *Medical Record*.

SENSIBILITY OF THE PERITONEUM AND ABDOMINAL VISCERA *

JAMES F. MITCHELL, M.D.
WASHINGTON, D. C.

Although earlier writers, both physiologists and surgeons, made passing mention of the fact that certain parts of the peritoneum and abdominal viscera are more sensitive than others, Lennander,[1] in 1901, first called attention forcibly to the fact that there is a distinct and constant contrast in the sensibility of the parietal and the visceral peritoneum. His first publication was elaborated by others until the time of his death. By an exhaustive and painstaking series of observations during operations, performed chiefly under local cocain anesthesia, he established the following facts: The parietal peritoneum is intensely sensitive to pain, but not to pressure, heat or cold. The abdominal viscera, on the other hand, possess no sense of pain. In other words, the visceral peritoneum and the abdominal organs, innervated only by the vagus or sympathetic nerves, are not sensitive to pain, and painful abdominal sensations are transmitted only by the phrenic, the lower six intercostals, and the lumbar and sacral nerves, which supply the parietal peritoneum. For the mesentery, his findings are not absolute, though he considered it also insensitive. By the natural application of these facts, Lennander offered hypotheses for the explanation of pain in various abdominal conditions, such as appendicitis, peritonitis or gastric ulcer. These ideas he expressed in a paper before the Section on Surgery of the American Medical Association in 1907, which may be summed up as follows: Pains do not originate within the abdominal organs themselves. Irritation of an abdominal organ first gives rise to pain when it has extended to sensitive tissue outside this organ. Pain then exists through an irritation of the parietal peritoneum. This may be mechanical, as in volvulus; chemical, as in absorption from an ulcer; or infectious, as by means of a lymphangitis in appendicitis, or the direct expulsion of contents from gall-bladder, stomach or intestine. Viscera involved in disease are quite as insensitive as sound ones, while the irritability of the parietal peritoneum is much increased by even a slight inflammation.

Lennander's work acted as a stimulus to investigators and there have appeared many exhaustive papers by surgeons, internists, physiologists and psychologists. Surgeons basing their opinions on findings during operations on human beings have, in the main, upheld Lennander's views. The general tendency is for animal experimenters to oppose them. Psychologists tend to take a middle path, and while admitting that for external stimuli the viscera may be insensitive, assert that nevertheless they possess a certain unlocalized sensibility to internal conditions.

The pain of ileus has been the subject of much discussion. Intestinal colic has been ascribed by Nothnagel[2] to anemia of the intestinal wall and to pressure on the nerves of the bowel wall in consequence of a tonic spasm of its muscular coat. Wilms[3] asserted that all those pains, which we are accustomed to term intestinal colic, are entirely due to the stretching of mesenteric attachments. Lennander found that he could stimulate a loop of human intestine until it became hard and blanched, and still there was no pain unless it tugged on the parietal peritoneum. This explains the fact that we often find dense adhesions between coils of intestine without any discomfort, and yet, when a movable piece of bowel is adherent to the fixed abdominal wall there is always pain. Lennander believed, however, that some forms of colic could not be explained by dragging alone, and these he attributed to a sliding of the parietal peritoneum on its very sensitive subserous tissue. A finger introduced into the abdomen and held firmly pressed against the parietal peritoneum of the anterior wall will not cause pain; but if the finger, while still in firm contact, is moved slightly from side to side, there will be intense pain. This I have often seen demonstrated in the use of a retractor dragged on by an inattentive assistant. We can thus see why a gradual, general distention may not be painful, while unequal distention of an obstructed intestine causes acute pain.

Innumerable tests made by surgeons at the operating table have shown that operative procedures may be painlessly carried out on practically any abdominal organ, provided the parietal peritoneum is avoided. Through gastric or intestinal fistulas the mucous membrane has been tested and has likewise been found to show no perception of touch, heat, cold or pain. Zimmermann,[4] in 1909, reported an extensive series of experiments on himself and on patients, in which the mucous membrane of the stomach and of the rectum was examined without the employment of any anesthetic. Through a stomach-tube or a rectal speculum the mucous membrane was irritated by means of pinching forceps, electrodes and the cautery. In the rectum, above 6 cm. from the sphincter, there was no response to touch, temperature, or electric stimulation; but great differences in pressure were felt. In the stomach likewise, he got no response, and here also there was only a sensation of fulness on great pressure. The esophagus he found sensitive to pressure and temperature, thus accounting for the sensation of warmth on taking hot or alcoholic drinks. This is in accord with the conclusions reached by Hertz, Cook and Schlesinger.[5] Schwenkenbecher,[6] in 1908, described an observation in which he took large doses of menthol, which produces in the mouth a feeling of intense cold. He noted that after the menthol passed the level of the larynx this feeling of cold was not experienced in any part of the intestinal canal until the sphincter ani was reached. He concluded from this experiment that the whole intestinal canal, except its upper and lower ends, is insensitive. Neumann,[7] on the other hand, found the stomach in women very sensitive to differences in temperature. How then can we account for the pain of gastric ulcer? It is well known that gastric ulcers can exist without pain, and their presence first be suspected through perforation or hemorrhage. Lennander asserted that a gastric ulcer remains painless so long as it is not accompanied by a lymphangitis; that the pains of hyperacidity are also due to absorption, by which irritating toxic or chemical substances are carried to the sensitive tissue of the abdominal wall. Mueller,[8] while admitting

that the stomach shows no reaction to touch, heat or pain, as far as external stimulation is concerned, nevertheless maintains that it does react to internal irritations. . . . He believes that the abdominal organs do possess sensation for necessary protection; as from chemical irritation by increased acidity in the stomach, or mechanical irritation by fulness or distention. This sensibility he attributes to the sympathetic nerves, which, though ordinarily not transmitting pain impulses, may do so under abnormal or diseased conditions. He attributes the pain of gastric ulcer, as well as the distress of hyperacidity without ulcer, directly to the action of the increased hydrochloric acid content on the nerves of the stomach wall; and explains the painlessness of latent ulcers by the probable absence of hyperacidity. Mueller's statement was almost immediately answered by Schmidt,[9] who put into his own stomach as much as 30 c.c. of a 2 per cent. solution of hydrochloric acid with absolutely no unpleasant sensations therefrom. The question thus seems far from settled.

The pelvic organs of women have been frequently tested by surgeons during operations under local anesthesia. Their findings have been mostly in accord with those of Lennander. Sampson,[10] Broese[11] and others are among those who have made observations in this field, Broese stating that the diagnosis of ovarian neuralgia should never be made. Mueller and Godscheider claim that pain impulses may be transmitted from these organs by the sympathetic nerve. Meumann,[12] from the psychologic viewpoint, reaches much the same conclusion as Mueller. He believes that we possess internal sensation, but that it is not accurately localized. The uncertainty of these sensations is nothing but their indefinite localization, which depends on the fact that we cannot see their point of origin.

In 1906 appeared the first absolute contradiction of Lennander's ideas. Kast and Meltzer,[13] then and in later publications, reported the results of their animal experiments, chiefly on dogs. Their principal method of examination was to open the abdomen under ether narcosis, and close the wound by means of temporary sutures, the animal then being allowed to regain consciousness thoroughly, when one or more of the sutures was cut, and tests made through a very small opening. Mechanical, thermic and electric irritations were employed and any possible mesenteric tug was carefully avoided. They concluded that the abdominal organs of dogs, examined through a small opening, are undoubtedly sensitive; that this sensibility rapidly decreases on exposure or withdrawal of the viscera, but increases again after exposure long enough to produce inflammation. In cats and rabbits the sensibility is the same, but even more fleeting, and weak animals show less than strong ones. They see no reason why their findings should not apply as well to human beings. In offering an explanation for the conclusions reached by Lennander and other surgeons, Kast and Meltzer suggested that: First, the examinations were made through a large opening after exposure to the air or withdrawal of the viscera, and second, that they were all made during operations under local anesthesia. They found that a small dose of cocain, injected subcutaneously or intramuscularly, exerts almost immediately a quieting effect on animals and produces a general analgesia, thereby causing the sensibility of the parietal, as well as the visceral peritoneum and of the viscera themselves, to disappear. Their experiments were repeated by Mueller,[8] who obtained exactly opposite results. Ritter,[14] on the other hand, verified the conclusions of Kast and Meltzer; while Hotz,[15] experimenting on dogs under morphin narcosis, reports that manipulations of even strangulated or peritonitic intestines do not cause any expression of pain, and manipulation of the mesentery causes pain only when a tug makes traction on its root. In 1907, before this section, I[16] reported two cases in which I had opened the abdomen in men without the use of any anesthetic, and found that there was the same contrast between parietal and visceral peritoneum as when cocain was used. Haim[17] had a similar experience after opening the abdomen under general anesthesia and allowing the patient to regain consciousness. These observations were given little weight by Kast and Meltzer in their paper of 1909, because they were too few in number and not made on perfectly normal individuals. Ritter's views as to the general effect of cocain have changed with his different papers. At first (1908) he agreed with Kast and Meltzer; then (1909) he stated that cocain is purely local in its action, and later, he reported some interesting animal experiments in which he found that by injecting 5 c.c. of a 1 per cent. solution of cocain into the crural vein of a dog, all painful sensations were wanting in from three to five minutes. Vessels or nerves could be painlessly tied, or the skin burned with the cautery. This general anesthesia lasted half an hour or longer, when the animals gradually became normal.

An interesting communication has appeared this year by Harrison.[18] Into a superficial vein on the back of his hand, he injected slowly, during a period of thirty minutes, 5 grains of cocain in a 2 per cent. solution. Dizziness and palpitation made it seem wise to stop with this amount. Tests were at once made and results corresponded in an incomplete way with those reported by Ritter on animals. Cerebration was normal, except for inability to keep the mind on one subject. Motor power was unimpaired. There was marked analgesia everywhere. A small incision was made on the anterior part of the leg. It could be felt and caused a mere trifle of pain. Two or three small nerves in the fat were cut, each causing a slight twinge of pain. He concludes that the analgesia was probably sufficient for the performance of operative procedures without great pain, but that the relatively enormous dose of cocain necessary for even imperfect results makes it impossible for human surgery. It cannot be conceived then that the small amount of cocain used in an ordinary laparotomy could have any influence on peritoneal sensibility.

Ritter (1909) assails Lennander's findings. He bases his opinion on animal experimentation under morphin narcosis, agrees in general with Kast and Meltzer, and believes that the sympathetic nerves transmit sensory impulses. An entirely new principle is introduced in his experiments, associating visceral sensation directly with the blood supply. The ligation of blood-vessels, he says, is the only means of testing which eliminates all possibility of error. He finds this painful in every instance. Mesenteric tug he eliminates by means of double ligation, the proximal ligature always causing pain, but the distal ligature only when it is applied first. All parts of the abdomen are thus sensitive, non-vascular parts less so than those rich in blood-vessels. The vessels themselves are most sensitive. Cocain acts only as a local anesthetic in the abdomen, and when applied about mesenteric vessels renders anesthetic the viscera supplied by them. Ritter believes the negative findings reported by surgeons to be due, not to cocain, but to the injury which the laparotomy does to the finer sensible nerve fibers in the abdominal cavity. This injury is important in the production of shock. He thinks it therefore wise when working in the abdomen under local anesthesia, to cocainize every vessel of any size before ligating it.

In a paper published in 1910, Nystroem,[19] a former assistant of Lennander, again champions his theories, and discusses in detail opposing contributions. He questions the value of animal experimentation, and calls attention to the opposite results obtained by different investigators in the same experiment, as well as the varying results with animals of different species. He repeated the test of Kast and Meltzer on animals, and was able to get no evidence of pain unless the mesentery was dragged on. He then made the same observation on a man during an operation for hernia. Under light ether narcosis the peritoneum was opened by a small incision. A loop of intestine was found presenting at the opening. The peritoneum was temporarily closed, and the patient allowed to regain consciousness. The parietal peritoneum was then found very sensitive, but the man was not aware of any irritation of the intestine unless the mesentery was pulled on. Nystroem concludes that the contradiction of Lennander's work is not to be unhesitatingly accepted, although he admits that there are many things which cannot yet be accurately explained. He suggests that further investigation of Ritter's idea of the relation between sensibility and blood-supply in the human abdomen is most important. Since reading Ritter's paper I have not had an opportunity of testing this except for the omentum, but I recall many cases in which large portions of vascular omentum have been painlessly excised, or sections of gall-bladder or liver removed for examination without complaint.

Daily experiences at the operating table, and in the after-care of patients whose abdomens have been drained, impress on us the greater sensitiveness of the parietal peritoneum. This is apparent even under ether narcosis. A patient may lie perfectly quiet during the manipulations of a gastroenterostomy, but will show evidence of disturbance when gauze pads which have been in contact with the abdominal wall are withdrawn, or when the viscera are replaced. In the production of shock, too, the greater influence of manipulation of the parietal peritoneum or mesenteric attachments is noticeable. This I have observed, especially in operations about the bile passages. Exposing, opening and draining a gall-bladder causes little disturbance in the patient's condition, but as soon as there is any extensive interference about the foramen of Winslow there is immediate evidence of shock. This region has been shown to be especially rich in spinal nerves, and I have found it most difficult to explore under local anesthesia. Likewise, a woman on whom I was doing a splenectomy for Banti's disease was in excellent condition until a ligature was tightened about the pedicle of the spleen, when she almost immediately passed into profound shock. If Ritter's view of blood-vessel-sensation association holds true, this might here be offered as an explanation. Mummery and Symes[20] have shown that manipulations of the parietal peritoneum and mesenteries in fully anesthetized animals produce shock much more rapidly than the same disturbance of the viscera. With local anesthesia it is very evident that only those procedures are painful which involve the parietal peritoneum or mesenteries.

A drain which lies against the abdominal wall is always more painful in its removal than one which only touches the viscera. We thus learned long ago, in the days of large gauze drains, to protect the peritoneal edges of our wound by tucking in rubber tissue. We can recall the pain resulting from the old method of suturing the gall-bladder to the peritoneum, and the consequent abandonment of this procedure. All these observations, made after opening the abdomen, are subject to the criticism that sensation may have been interfered with by the laparotomy itself.

Kast and Meltzer, in drawing their conclusions, end by stating that "surgical experiences on men offer no proof that the viscera of normal man in the normal closed body can feel no pain." While this is naturally a hard condition to answer, it has seemed to me that much might be learned by the careful analysis of all abdominal pains in patients about to be subjected to laparotomy. It has, therefore, been my custom for the past few years to write down the findings before operation, and make also a written prediction as to what was to be expected on opening the abdomen. A comparison of these predictions with the operative findings has given interesting results in support of the marked contrast between visceral and parietal peritoneal involvement. Many referred pains may be explained by the relation of the involved organ to the parietal peritoneum. Thus the first pain of an acute appendicular attack is most often located in the epigastrium. Time and again I have found with the abdomen open under local anesthesia that this pain could be accurately reproduced by traction on the mesentery of the appendix. The pain is, under these circumstances, accompanied by nausea, just as is so often seen in irritating the neck of a hernia sac. While doing a cocain appendectomy on a physician, Dr. S., I obtained his consent to some tests, the nature of which he did not know. He was anxious to watch the operation and see his appendix in place, and so was allowed to have his head raised for this purpose. The appendix presented readily at the opening in his unusually thin abdominal wall. It was clamped across, and caused no inconvenience. Then, by making traction on the mesentery, I could at will cause him to sink back with marked pallor, nausea, and complaint of violent pain in the epigastrium, which he described as "my old friend." These phenomena disappeared when the mesentery was released, and he was able to watch the completion of the operation. In a case of gall-bladder fistula with total occlusion of the cystic duct, as shown by a later operation, I was able, by injecting into the gall-bladder hydrogen peroxid and placing a finger over the fistula, to cause the typical pain of gall-stone colic. The man complained of agonizing pain about the right shoulder blade, which immediately disappeared when the finger was removed from the opening. I believe this pain to have been caused by traction of the distended gall-badder on the posterior peritoneum, and not by the mere distention itself; for a probe introduced into the gall-bladder and pushed with some force against its walls did not cause discomfort. I have seen the referred pain of ovarian disease, that is, down the inner aspect of the thigh, in an interesting case.

[20] Mummery and Symes: Brit. Med. Jour., 1908, ii, 790.

This boy (Mr. S., Case 1,034), aged 19, had been operated on eight years before for supposed appendicitis. The appendix was not found, and there was no pus, but apparently after considerable traumatism the wound was drained on acount of oozing from torn surfaces. He came to me complaining of frequent attacks of abdominal pain and nausea, which were not accompanied by fever. A careful analysis of his pains showed that they could be divided into three distinct groups: First, epigastric pain; second, diffuse pain in the region of his scar near the iliac crest, and third, pain down the inner side of his right thigh, simulating referred ovarian pain. It was concluded that there were three sets of adhesions between movable organs and parietal peritoneum; first, about the appendix; second, about the scar, and third, to the pelvic wall corresponding to the outer side of the broad ligament. At operation through a rectus incision there was found an appendix kinked on itself and bound by dense adhesions; adhesions between the cecum and parietal peritoneum about the scar, and a long tongue of omentum adherent to the pelvic wall about the iliac vessels. The appendix was removed, the omentum ligated and divided, and some of the adhesions about the scar separated, but raw surfaces left. The boy has remained well now for two years and has had no return of pain in the epigastrium or thigh, but occasionally some pain in the region of the old scar.

In acute conditions the findings are quite as constant. True muscle spasm is always due to inflammation of the anterior and lateral parietal peritoneum, and it is possible to make out accurately the extent of this involvement. While there may be some resistance to pressure on deep palpation in centrally located lesions, true protective muscle spasm comes only from inflamed parietal peritoneum. By the character and amount of pain and by the resistance to palpation, it is possible to tell before operation whether the lesion will be found deeply situated, as between omentum and intestinal coils, or directly against the parietes. The two following cases, operated on the same day, will serve as illustrations.

Mrs. Y., Case No. 1,086, gave a history of slight pain, referred to the umbilicus, followed by nausea and vomiting, and later by temperature. The pain was at no time very severe and had entirely disappeared on the third day of her illness. Examination showed a mass in the right iliac fossa. This was only slightly sensitive on deep pressure. There was no rigidity of the abdominal wall and no suggestion of muscle spasm. She was running a high temperature and it was predicted that the condition was an appendix abscess, well protected and not involving the parietal peritoneum. At operation there were found several ounces of foul pus, entirely walled in between intestinal coils and covered over by omentum. There were nowhere any adhesions to the parietal peritoneum. The tip of a long appendix, gangrenous and perforated, was lying in the abscess cavity. The base of the appendix was outside and entirely uninvolved.

Mr. F. (Case 1,084) was brought into the hospital with a history of forty-eight hours' illness, starting with violent pain about his umbilicus and in the right side, accompanied by nausea, vomiting and high temperature. His physician stated that the pain was so severe that it was necessary to administer chloroform before bringing him to the hospital. Examination showed respiratory movements on the right side limited and acute tenderness, rigidity and muscle spasm throughout the whole right flank, extending nearly to the costal margin. In this instance it could be definitely stated that the appendix was lying in contact with the parietal peritoneum and that there was involvement of the parietal peritoneum of the whole right flank. At operation, omentum, cecum and ascending colon were found adherent to the parietal peritoneum, limiting an abscess lying directly against the lateral abdominal wall. A gangrenous and perforated appendix was found, running up anterior to the colon, its tip adherent to the edge of the liver, thus lying in its whole length directly against parietal peritoneum.

Mr. S. (Case 977) was seen in an acute illness of several days' duration, which had been diagnosed by the attending physician as cholecystitis. There was no jaundice; but his pain, which had started in the epigastrium, was later most intense high up in the right flank and referred to the right shoulder blade. At operation there was found an abscess between the ascending colon and parietal peritoneum, containing a perforated appendix whose tip was adherent to the gall-bladder.

Another interesting patient came into the hospital with strangulation of a right inguinal hernia, accompanied by a temperature of 103 F. The hernia was reduced by an intern. Two days later the patient still had temperature and high leukocytosis, although his pain had entirely disappeared, and there was no tenderness or rigidity on pressure. Operation was done for the cure of his hernia. Through the internal ring the appendix was palpated and there was found a mass about its tip entirely encircled by a tongue of omentum. The appendix and omental mass were delivered through the ring and removed without separating the adhesions. The specimen showed a small abscess about the perforated appendix tip, which, however, had given no symptoms of pain, because entirely protected from parietal peritoneum by the surrounding omentum.

Our records show numerous similar cases, which, to me certainly, offer an evidence of a definite contrast in the sensibility of the parietal and visceral peritoneum in the unopened abdomen in man. Without denying the usefulness of animal experimentation in this particular field, we must insist that its results cannot outweigh the mass of surgical evidence. We agree with Nystroem that, while there are some weak points in Lennander's hypotheses, they appear to give a more rational explanation of the phenomena of abdominal pain than does the theory depending on an imaginary pain-carrying power of the sympathetic nerves.

1344 Nineteenth Street.

ABSTRACT OF DISCUSSION

Dr. W. LeMoyne Wills, Los Angeles: Through the courtesy of Dr. Mitchell I have read his paper and have found that he has quoted the experimentation and literature of the last ten years, much of which I could not have obtained if I had wanted to; and it seems to me from the reading of the paper that it is the "Lennander theory" against the field, and most of us are willing to accept Lennander, and we must accept his theory until it is contradicted by equally good authority and observations. The German theorists and experimentalists have not gone so far as Dr. Mitchell has in his endeavor to make the experimentation and clinical findings of practical use. He has covered the ground so thoroughly that it is unnecessary to say more than that it is an instance of American ingenuity in turning the theories and experiments of foreign investigators to account in the way of securing the most practical results. If, as Dr. Mitchell has tried to show, he can make the diagnosis by pain more practical and useful, he will do us a great service. The average doctor and surgeon and patient care little about the hair-splitting distinctions as to whether it is this nerve or that nerve, or this traction or that traction, that produces the pain. What they want is practical deductions from these experiments, which will enable the physician and surgeon to make a better diagnosis, and thereby operate more successfully and get better results.

Balsam of Peru or Salvador.—The "balsam of Peru," so much used in medicine and surgery, comes from a tropical tree found in the republic of Salvador, which exports 130,000 pounds of the product yearly, half of which goes to Germany, nearly as much to the United States, with the small remainder to France.—*Daily Consular and Trade Reports.*

THE SANITARY RECORD OF THE MANEUVER DIVISION *

J. R. KEAN, M.D.
Lieutenant-Colonel, Medical Corps, U. S. Army
WASHINGTON, D. C.

Since July 10 the most of the organizations composing the Maneuver Division of regular troops at San Antonio, Texas, have been returned to their stations.[1] It is, therefore, an appropriate time to review the health conditions and sanitary administration of this camp, which has established a record that is unique in our Army for the smallness of its sick-list, the excellence of its sanitary [illegible] and the completeness in organization of [illegible] The division consisted of eight regiments of infantry, two of cavalry, two of artillery, and the usual quotas of engineers, signal corps, and hospital corps. The latter had in addition to the regiment, four ambulance companies and four field hospitals. These were complete in equipment so far as the Medical Department could supply them, but one ambulance [illegible] field hospital were never supplied by [illegible] Department with their mounts and draft animals. As regards personnel, although every garrison in the United States was stripped to an irreducible minimum to supply medical officers and hospital corps men for these organizations, there was a deficiency of twenty-one medical officers and 129 men below the authorized strength. This did not seriously impair the efficiency of the medical service of the division for field work, as it was itself much below its tactical strength, having only about 12,000 men instead of nearly 20,000, which it should have at war strength. These facts demonstrated clearly, however, the numerical inadequacy of the medical establishment of our Army, and if a second division had been called out, as at one time seemed probable, the situation in this respect would have been acute. The complete medical equipment and supplies for the division, including a base hospital of 500 beds and two evacuation hospitals of 324 beds each were shipped from the Field Medical Depots at Washington and St. Louis, accompanied by a detachment of the Hospital Corps to prevent loss or side-tracking, and arrived at San Antonio before the last troops were detrained.

SANITARY ARRANGEMENTS

A portable field laboratory was for the first time added to the medical equipment of this division for diagnostic and sanitary purposes. The base hospital was established at the neighboring post, Fort Sam Houston, for the reception of serious cases, but the evacuation hospitals which were intended for use on the line of communications, not being needed, were not manned or opened. The chief surgeon of the Division was Col. H. P. Birmingham, and the sanitary inspector Major Paul F. Straub, both of the Medical Corps, U. S. Army, and the latter a member of the General Staff.

The disposal of wastes is a matter of elementary importance in camp life and new and interesting developments were reached in this camp. In the vexed question of disposal of excreta, the old latrine pit, which had been thoroughly discredited by the better experience of the Spanish war was succeeded by the trough filled with milk of lime and emptied by an odorless excavator wagon and pump which was devised by the distinguished board which investigated the camp epidemics of typhoid fever in 1898 and of which Reed, Vaughan and Shakespeare were the members. This system broke down in rainy or freezing weather and in sandy soils and was gradually displaced by the theoretically perfect, but practically cumbrous incinerators, which did good service in fixed camps and with skilled handling, but were not mobile and were very costly. The mobilization of March 6 was so unexpected and so rapid that no time was given for the purchase and erection of these elaborate constructions and so a system was adopted which has been previously tried on a small scale. A narrow, deep trench, 18 to 24 inches wide, is dug and over it is placed a box seat, entirely fly-proof, with self-closing covers and a urinal at one end. This sink-box, as Harvard terms it in his excellent "Military Hygiene," can be knocked down for transportation, is movable, and is removed once a day, and the pit burned out with hay sprinkled with crude petroleum. The box was at the same time cleaned and then replaced. The contents of the pit were in this way sterilized so as to give no putrefactive odor after even three months of use. Besides the greater simplicity, mobility and quickness of installation of the sink-box as compared with incinerators, the Quartermaster's Department estimated that the cost of the sink-box system was $900 a month for the whole camp, whereas incinerators of an approved type would cost for material and labor $30,000 a month. The kitchen wastes, both solid and liquid, were also consumed by fire, in a kitchen crematory which consisted of a shallow pit a foot deep, 4½ feet long, and 2½ feet wide, filled to the level of the earth with broken stone and surrounded by a wall of clay or stones a foot high. A fire was kept burning on this and consumed all garbage thrown on it while the heated stones quickly evaporated the slops.

Horses in camp were tied side by side to a heavy rope called a picket-line and so their droppings were easily collected and with the straw bedding hauled away and burned. The picket-line areas were also sterilized once a week by burning them over with straw and crude petroleum, thus effectually disposing of the fly larvæ and of all odors. Ten gallons of oil were used for each burning of a picket line. These several precautions effectually kept down the number of flies and afforded no opportunity for their access to infectious material.

The sanitary police of the camp in other respects also was rigidly supervised by the medical officers, so that this crowded camp site, which had been used continuously for four months, when vacated presented nothing offensive to sight or smell.

The water-supply was from the water system of Fort Sam Houston and was artesian in origin and entirely above suspicion.

HEALTH OF THE TROOPS

The health of military commands is usually measured by the constantly non-effective rate which represents the average number constantly sick in each thousand men. This was for the Maneuver Division 22 per thousand up to the first of July, and its smallness can be appreciated when it is stated that this rate was 34 for all troops in the United States for the year 1910. In other words, the health of these soldiers in camp, sometimes living in deep mud and at other times in clouds of dust and under a semitropical sun, was better than in barracks surrounded by the comforts and sanitary appliances of post life.

The largest cause of morbidity was venereal diseases (4 per thousand), and next came measles and mumps (3 per thousand), the latter affecting almost exclusively the

newly arrived recruits. The actual number of admissions for the more important camp diseases were: typhoid fever, two; malaria, nine, all benign tertians; simple diarrhea, 119; dysentery, twenty-nine.

TYPHOID PROPHYLAXIS

Perhaps one-fourth of the troops arrived at San Antonio already immunized by voluntary antityphoid inoculations given them at their posts. It was concurrently determined by the Division Commander and the War Department that the time had arrived to make this procedure compulsory for troops taking the field, and it was so ordered and carried out as rapidly as the prophylactic culture could be supplied from the laboratory of the Army Medical School. The technic was simple. The site of puncture, usually the outer side of the left arm, was sponged off with alcohol and a small area sterilized with tincture of iodin, the injection made with a sterile syringe and the puncture sealed with collodion. The first dose is 0.5 c.c., the second and third being 1 c.c. each. An interval of ten days is allowed between doses, the entire procedure thus taking twenty days. The injection is made into the subcutaneous connective tissue and not into the muscles. There was practically no puncture infection, and the reaction was mild or absent in 90 per cent. of the cases treated. In no case was it followed by serious results. There were up to July 1, 8,097 men immunized.

* In addition to the above a civilian teamster, not immunized, was admitted for typhoid fever in April.

† This patient, a private of the hospital corps, had not completed his immunization, having taken only two doses. The case was very mild and would perhaps have been overlooked but for the rule that blood cultures were made in all cases of fever of over forty-eight hours' duration. The Widal reaction has no diagnostic value in immunized persons, as all respond to it. Forty-nine cases of typhoid fever with nineteen deaths were reported as occurring in the City of San Antonio during this period.

The immense advance in camp sanitation and particularly the value of this protective measure can be estimated by comparing the typhoid incidence of this camp with that of the Second Division, Seventh Army Corps, which was organized at Jacksonville, Fla., about June 1, 1898, and remained there in camp until October; some of the regiments leaving in September. This division was not conspicuously unfortunate in its typhoid record for that time, and is selected because of the close similarity of its conditions of service to those of the Maneuver Division. The two divisions were encamped in nearly the same latitude and for about the same length of time, and each had a good camp site and an artesian water-supply of unimpeachable purity. While the period in camp of the Second Division, Seventh Army Corps was later in the year, the number of men involved is larger for the Maneuver Division. The accompanying table referring to the former is taken from the celebrated "Report on Typhoid Fever in U. S. Military Camps in the Spanish War," by Reed, Vaughan and Shakespeare, Vol. 1, page 609.

REPORT ON 140 RECENT CASES OF PSORIASIS IN PRIVATE PRACTICE UNDER A STRICTLY VEGETARIAN DIET*

L. DUNCAN BULKLEY, A.M., M.D.
Physician to the New York Skin and Cancer Hospital, Consulting Physician to the New York Hospital, etc.
NEW YORK

In spite of repeated communications[1] on the subject the medical profession still does not seem to realize the value of a strictly vegetarian diet in psoriasis; and yet I could refer to many intelligent patients in private practice who have said, "You may quote me as a striking instance of the unquestionable value of this element in treatment."

It occurred to me, therefore, to keep a list of patients in private practice whom I had observed and treated during the past two years, and who have been under a vegetarian diet, and, after studying their records, to present the results obtained; the total number of the cases is 140. Some of the patients have been under observation and more or less treatment for many years; the larger proportion of them were first seen during the past two years; but, as will be mentioned later, the older and the newer cases alike confirmed the value of a strictly vegetarian diet, often in a very striking manner. It should be stated that careful notes were recorded of all these cases, and full entries made at each and every visit; I may add that most of the cases to be analyzed were also watched by my office associate, Dr. Paul E. Bechet, who is equally impressed with myself in regard to the beneficial effect of the plan advocated.

Psoriasis is such an inveterate disease that many patients applying for treatment are often convinced by what they have heard from physicians and others that the disease is incurable, and it is often very difficult to get the patient to submit to the proper dietary treatment for a long enough period to secure perfect results. Moreover, it not infrequently happens that even while maintaining a strictly vegetarian diet, there will be an outbreak of the eruption, more or less severe, and the patient is naturally discouraged, and may drop the diet, not recognizing that there are other causes which may

disturb the metabolism and induce the recurrence of the disease. This subject will be more fully considered later.

Whenever I have presented the subject some one has always opposed the vegetarian plan of treatment by referring to the constantly quoted report of a certain Dr. Passavant, who asserted that psoriasis could be cured by an exclusively meat diet. Although I have already exploded this fallacy on a former occasion,[2] I feel that I must briefly state the facts in order that this contention may be set at rest: for the text-books all refer only to this single report, published over forty years ago, and never confirmed by any one since, as far as I can find in literature, whereas many have more or less supported the value of a strictly vegetarian diet in psoriasis.

The facts are briefly these. In 1867 Gustav Passavant of Frankfort, Germany, in an open letter to Prof. F. Von Hebra,[3] reported that having suffered for twenty-five years from psoriasis he was soon free from it after entering on an almost absolute meat diet, including soup, pork, fats, cod-liver oil, milk and bacon, and practically no vegetables or bread; he advised also against wine, beer, coffee and tea, and spices. He cited one case of squamous eczema also relieved by this treatment.

There are a number of points in connection with this brief report which quite invalidate any importance which might be attached to it. Dr. Passavant does not mention if possibly he used any treatment, internal or external, in connection with the diet; then, he does not state if the improvement in his condition lasted any length of time, or if he had any return of the eruption, either under the diet or without it; he does not mention the season of the year, for we know that psoriasis will sometimes disappear spontaneously with the changing season; finally, on analyzing the diet mentioned, it is not really a meat diet, as he emphasizes pork, fats, cod-liver oil, milk and bacon, which contain very little nitrogen. However, he mentions one single other case, and that of eczema, which was benefited by his plan of treatment.

On the other hand, Professor Hebra,[4] to whom Dr. Passavant addressed his open letter, ridiculed the claim made, some years after its publication, and, as far as I can find, there has been no subsequent corroboration in literature of the correctness of the claim of Passavant that psoriasis can be cured by a meat diet. Surely if there were any truth in it, some proof would be forthcoming in the forty-four years which have elapsed since its publication. On the other hand there are abundant, though brief, allusions in literature as to the injurious effect of excessive meat-eating in psoriasis. My experience, dating back, some of it, for twenty-five years, shows conclusively that not only does a meat diet increase psoriasis, but that an absolutely vegetarian diet is of the very greatest benefit in this disease, and in certain cases is capable of alone causing the disappearance of a long-standing eruption, without the use of any internal or external medication whatever. It is sincerely to be hoped that the senseless reference to the Passavant incident will now disappear from our text-books and literature, as they lead only to confusion and misjudgment.

Psoriasis is undoubtedly one of the most rebellious of all affections appearing on the skin, discouraging alike to the physician and patient. While a certain few cases will yield admirably to well-directed treatment, and perhaps remain free for a varying length of time, the disease is pretty sure to return in a very large proportion of instances, under all the forms of treatment which have hitherto been recommended in the text-books and literature. Certain it is that local treatment alone, which is often very effective when properly carried out, can accomplish nothing in the way of a permanent cure.

Psoriasis is not so very common an eruption, as it forms, generally, about 3.5 per cent. of cases appearing in various localities. It is rarely found, however, in the warmer climates, and during a prolonged trip to the far East I could not learn of any cases at all among the natives in various countries who lived mainly on a vegetarian diet, principally rice.[5] The disease affects all ages, and the sexes about equally, as may be seen from Table 1, which represents separate patients, with no duplicates, as far as is known.

TABLE 1.—AGE AT TIME OF CONSULTATION

	Private Practice			Public Practice			
Age (years)	M.	F.	Total	M.	F.	Total	Grand Total
0-5	1	2	3	8	7	15	18

75-80	1	..	1	2	..	2	3
Age unknown	3	..	3	..	7	7	10
	393	314	707	979	957	1,936	2,643

The 707 cases in private practice occurred among 18,705 miscellaneous skin cases, giving a percentage of 3.7, and the 1,936 in public practice among 49,622 cases, making over 3.8 per cent. It will be seen that patients come at all ages for treatment, there being even three between 75 and 80 years of age, while by far the largest proportion were between 20 and 30 years of age, namely 858, or almost one-third of the whole.

The age at which the eruption is likely to develop first is seen in Table 2 taken from patients in private practice.

TABLE 2.—AGE AT FIRST APPEARANCE OF PSORIASIS
PRIVATE PRACTICE

	Number		
Age (years)	Male	Female	Total
1/3	1	..	1
1	3	..	3
1–2	2	3	5

In such a disease as psoriasis, and with private patients, who cannot always be controlled or seen as often or as long as desired, it is very difficult to make concise and correct statements in regard to the carrying out of any particular line of treatment, or the results therefrom. But Table 5 will give some idea of the length of time during which a vegetarian diet has been carried out, more or less strictly, by the patients whose cases are under consideration.

TABLE 5.—DURATION OF VEGETARIAN DIET

	68	72	140

It is actually true that quite a number of these patients have continued a strictly vegetarian diet for months and even years, and I have frequently been told that they would not return to a mixed diet under any consideration. In some instances they have relaxed more or less, with perhaps but little ill effect on the condition of the skin, when all other elements of treatment were rightly carried out. But time and again patients who have relapsed into free meat-eating have returned with a fresh outburst of eruption, or great aggravation of any that had remained, and they intelligently recognized the cause, and have willingly taken up the vegetarian diet again, because of the great benefit which they had previously experienced from it.

The question arises as to the length of time it is necessary to continue the vegetarian diet. I am accustomed to tell my patients that this may be indefinitely; for if a faulty nitrogenous metabolism and excretion is at the bottom of the eruption, as it seems to be, this may recur whenever the intake of proteids exceeds the power of the system to handle them.

In some instances a return to a moderate mixed diet has not seemed to increase the tendency to the eruption, but in very many cases it has been recorded that any indulgence in a great amount of nitrogenous diet has caused a return of the skin lesions. So that we must infer that with a certain small proportion of human beings the organs are not able properly to assimilate much proteid substance.

It may be asked if the improvement observed to occur on a vegetarian diet bears any relation to the seasons of the year, as it is well known that psoriasis will often disappear at certain seasons. It may be answered that this is not the case. In the cases here analyzed the patients have been treated and watched throughout the year, and the improvement occurs shortly, irrespective of the season.

It may also be questioned as to whether the improvement observed was not due to some medication, internal or external. In reply I may say that this has been tested in a number of patients, over half a dozen, and these mostly inveterate cases, some of whom were very skeptic, owing to long years of unsuccessful treatment elsewhere. Explaining the matter fully, these patients have had absolutely no other treatment, internal or external, and have watched with great interest as certain lesions have ceased to scale, then faded, and finally disappeared entirely, leaving only a stain, which ultimately ceased to exist. This has been verified time and again by my associate, Dr. Bechet.

It is true, however, as remarked before, that there will sometimes be a recrudescence of the eruption to a greater or less extent, even while the patient is supposed to be under a rigid vegetarian diet; but I have never seen an outbreak nearly so severe or so persistent as previous ones; the lesions will be small and much less pronounced, and will commonly yield quite readily to appropriate treatment, dietary and medicinal.

This recurrence of eruption may be accounted for in several ways, and does not at all weaken the argument for a vegetarian diet in psoriasis. First, it is always possible that the patient may not have always adhered to the restricted diet as absolutely as reported. Second, the details of an exactly proper vegetarian diet have not yet been all worked out, and it is quite possible that some articles in the vegetable kingdom may lead to the faulty metabolism which is at the bottom of psoriasis. Third, there may be other causes also at work, as yet unrecognized, which favor the eruption. Fourth, there may be such a wrong action of some of the internal organs that even a purely vegetarian diet does not secure a perfect blood condition. (It will be seen from what has preceded that I regard psoriasis as a constitutional and not a purely local affection, although I recognize that the lesions on the skin may be due, in part, to the action of some of the microscopic organisms which abound on the surface, which operate when the soil has become suitable. It would lead too far from our subject to discuss the matter further, and to present the indubitable proof of this thesis.)

We may now very briefly consider the physio-pathologic basis for a vegetarian diet in psoriasis, and some of the principles underlying its successful treatment.

Perverted metabolism, and hence disordered nutrition, is the basis of much disease, whether it be caused by an erroneous intake of nutritive substances or the faulty disposition of them by the various organs of the system.

If we knew as much about the fluid composition of the blood as we do about its cellular elements, and should analyze it frequently, we could undoubtedly determine more about the true pathogeny of disease. But in the urine we have a most wonderful indicator of the blood-state, and if its oft-changing conditions are minutely studied often enough, and intelligently interpreted, we can know much more of the processes of metabolism than can be learned in any other way. Formed as it is directly from the arterial blood, after this has been prepared by the various organs and finally aërated by the lungs, and is on its way to nourish the tissues, the kidney secretion is to be studied in another light than simply as an excretory product. By the different proportions of its many ingredients it represents to us to a certain degree the composition of the blood itself as the kidneys have found it, and the result of their efforts to purify it.[7]

Time fails to permit entering at all largely into the interesting subject of the condition of the urine continually found in patients with psoriasis; suffice it to say that the average of a very large number of carefully made, volumetric analyses showed deviations from the normal which were of the utmost importance, all looking towards an imperfect metabolism of nitrogenous elements. The average specific gravity was 1.026, 1.0[illegible] to 1.040 being not uncommon, and the acidity [illegible] and that it is not so uncommon in childhood, there being 109 patients or over 15 per cent. in whom it appeared up to 10 years of age; but in the next decade there were 238 cases; it may also develop first quite late in life, as there were twenty-five patients over 50 years of age. The most common period for its first appearance was between 15 and 20 years of age.

---

[7] Some Problems in Metabolism Occurring in Certain Diseases of the Skin, Jour. Cutan. Dis., April, 19

As is well known, when once well developed, psoriasis tends to remain indefinitely, and Table 3 shows the duration of the disease before coming under observation, in the patients in private practice.

TABLE 3.—DURATION BEFORE COMING

PRIVATE PRACTICE

	Number		
Age	Male	Female	Total
Under 1 year	51	46	97

Here we see a record of its persistence, twenty, thirty or even fifty years, and undoubtedly these numbers would be much larger were it not that so many patients become utterly discouraged, and relatively few of the many existing cases seek further relief after it has persisted for many years, often in spite of varied treatment.

Table 4 illustrates this point in regard to the patients in private practice. There were 152 who were seen only once, many of them in consultation, but of those who were treated there were 338, or over 60 per cent., who were treated less than one year, which is certainly not long enough to effect a change of system necessary to secure freedom from psoriasis. In many of those who were long under observation the records show that they were often irregular and careless in treatment, and many of them were seen before the strict vegetarian diet was rigidly enforced.

TABLE 4.—DURATION OF OBSERVATION IN PRIVATE PRACTICE

Vegetarian diet for health is no new proposition, and needs no defense or explanation; the literature regarding it is extensive, and its positive value has been frequently demonstrated. All are aware that repeatedly vegetarians have far outstripped meat-eaters in athletic contests, while the reverse is almost unknown. The mass of human kind have always subsisted largely or entirely on the products of the ground, and in animal life all work is done on food from the vegetable kingdom.

On the other hand, the consumption of much meat is of relatively modern date, with some exceptions, and is particularly common in cities, the mass of workers in rural districts subsisting chiefly on vegetarian products.

Nor need we dwell long on the injurious effects of a too highly nitrogenized diet on the human system, which has long been recognized and has had able exponents. All are familiar with the necessity of curtailing meat diet in many conditions of the system, and writers have repeatedly called attention to its influence in the production of cancer; the relative absence of cancer among the natives in rice-eating countries, which I also observed in the far East[5] is striking evidence in this direction.

The relation of meat-eating to psoriasis is also no new observation. Brief mention of it has occurred in literature for some time, and over twenty years ago,[6] at the First Congress of Dermatology and Syphilology, in Paris, in 1889, I stated that "excessive meat-eating will also increase the disease, which will frequently yield with much greater rapidity, under the same treatment as before, when the amount of meat taken is lessened, or when it is entirely cut off," as I had observed in private cases for some years. Since that time I have watched and studied the matter continuously, both in public and private practice, mainly the latter, and have reported favorably in regard to the same repeatedly, with increasing confidence; and this is especially true since I have been enforcing the diet most rigidly during the last two years, during which time I have kept the special record of these cases, as already referred to.

During this period I have observed 140 cases of psoriasis who were placed on a strictly vegetarian diet; there were sixty-eight males and seventy-two females, of all ages from 9 to 70 years. The patients have had the disease for varying lengths of time, though there were only ten who had been affected for less than one year; thirty-three had had it for from one to five years, thirty-six from five to ten years, and many for a great length of time, even up to forty years. I may here say, however, that I have seen quite as startling results in those who have been very long afflicted as in recent cases, provided there has been equal faithfulness to treatment.

In regard to the faithful carrying out of the dietetic treatment there have been, of course, varying degrees of fidelity in different patients, but it is interesting to note how willing those who have suffered from the disease for some time are to accede to the plan which offers them a prospect of freedom from their rebellious complaint; on the other hand, in some of the more chronic cases, the patients from their former experience have become so skeptical as to such hopes that it is often very hard to get them to persist faithfully in the diet; while those who have only begun to suffer from psoriasis find it difficult to believe that such a radical change in their mode of life is necessary.

Of the cases here analyzed, in twenty-one the patients were seen but once and must be excluded from consideration; twenty-five were seen but a month or less, and no ultimate conclusions can be drawn from them. Records show, however, that in some of them the almost immediate improvement in the character and appearance of the eruption indicated the benefit of the treatment, and quite probably some of them may have persisted in the diet and possibly may have become freed from the eruption.

As far as can be learned sixty-one patients or nearly one-half the entire number of those whose cases are analyzed, were wholly faithful to the vegetarian diet during the period while under observation, and twenty-four were recorded as fairly faithful.

---

[6] Tr. First Internat. Cong. Dermatol. and Syph., Paris, 1889, p. 892.

In such a disease as psoriasis, and with private patients, who cannot always be controlled or seen as often or as long as desired, it is very difficult to make concise and correct statements in regard to the carrying out of any particular line of treatment, or the results therefrom. But Table 5 will give some idea of the length of time during which a vegetarian diet has been carried out, more or less strictly, by the patients whose cases are under consideration.

It is actually true that quite a number of these patients have continued a strictly vegetarian diet for months and even years, and I have frequently been told that they would not return to a mixed diet under any consideration. In some instances they have relaxed more or less, with perhaps but little ill effect on the condition of the skin, when all other elements of treatment were rightly carried out. But time and again patients who have relapsed into free meat-eating have returned with a fresh outburst of eruption, or great aggravation of any that had remained, and they intelligently recognized the cause, and have willingly taken up the vegetarian diet again, because of the great benefit which they had previously experienced from it.

The question arises as to the length of time it is necessary to continue the vegetarian diet. I am accustomed to tell my patients that this may be indefinitely; for if a faulty nitrogenous metabolism and excretion is at the bottom of the eruption, as it seems to be, this may recur whenever the intake of proteids exceeds the power of the system to handle them.

In some instances a return to a moderate mixed diet has not seemed to increase the tendency to the eruption, but in very many cases it has been recorded that any indulgence in a great amount of nitrogenous diet has caused a return of the skin lesions. So that we must infer that with a certain small proportion of human beings the organs are not able properly to assimilate much proteid substance.

It may be asked if the improvement observed to occur on a vegetarian diet bears any relation to the seasons of the year, as it is well known that psoriasis will often disappear at certain seasons. It may be answered that this is not the case. In the cases here analyzed the patients have been treated and watched throughout the year, and the improvement occurs shortly, irrespective of the season.

It may also be questioned as to whether the improvement observed was not due to some medication, internal or external. In reply I may say that this has been tested in a number of patients, over half a dozen, and these mostly inveterate cases, some of whom were very skeptic, owing to long years of unsuccessful treatment elsewhere. Explaining the matter fully, these patients have had absolutely no other treatment, internal or external, and have watched with great interest as certain lesions have ceased to scale, then faded, and finally disappeared entirely, leaving only a stain, which ultimately ceased to exist. This has been verified time and again by my associate, Dr. Bechet.

It is true, however, as remarked before, that there will sometimes be a recrudescence of the eruption to a greater or less extent, even while the patient is supposed to be under a rigid vegetarian diet; but I have never seen an outbreak nearly so severe or so persistent as previous ones; the lesions will be small and much less pronounced, and will commonly yield quite readily to appropriate treatment, dietary and medicinal.

This recurrence of eruption may be accounted for in several ways, and does not at all weaken the argument for a vegetarian diet in psoriasis. First, it is always possible that the patient may not have always adhered to the restricted diet as absolutely as reported. Second, the details of an exactly proper vegetarian diet have not yet been all worked out, and it is quite possible that some articles in the vegetable kingdom may lead to the faulty metabolism which is at the bottom of psoriasis. Third, there may be other causes also at work, as yet unrecognized, which favor the eruption. Fourth, there may be such a wrong action of some of the internal organs that even a purely vegetarian diet does not secure a perfect blood condition. (It will be seen from what has preceded that I regard psoriasis as a constitutional and not a purely local affection, although I recognize that the lesions on the skin may be due, in part, to the action of some of the microscopic organisms which abound on the surface, which operate when the soil has become suitable. It would lead too far from our subject to discuss the matter further, and to present the indubitable proof of this thesis.)

We may now very briefly consider the physio-pathologic basis for a vegetarian diet in psoriasis, and some of the principles underlying its successful treatment.

Perverted metabolism, and hence disordered nutrition, is the basis of much disease, whether it be caused by an erroneous intake of nutritive substances or the faulty disposition of them by the various organs of the system.

If we knew as much about the fluid composition of the blood as we do about its cellular elements, and should analyze it frequently, we could undoubtedly determine more about the true pathogeny of disease. But in the urine we have a most wonderful indicator of the blood-state, and if its oft-changing conditions are minutely studied often enough, and intelligently interpreted, we can know much more of the processes of metabolism than can be learned in any other way. Formed as it is directly from the arterial blood, after this has been prepared by the various organs and finally aërated by the lungs, and is on its way to nourish the tissues, the kidney secretion is to be studied in another light than simply as an excretory product. By the different proportions of its many ingredients it represents to us to a certain degree the composition of the blood itself as the kidneys have found it, and the result of their efforts to purify it.[7]

Time fails to permit entering at all largely into the interesting subject of the condition of the urine continually found in patients with psoriasis; suffice it to say that the average of a very large number of carefully made, volumetric analyses showed deviations from the normal which were of the utmost importance, all looking towards an imperfect metabolism of nitrogenous elements. The average specific gravity was 1.026, 1.030 to 1.040 being not uncommon, and the acidity was invariably high, often three or more times the normal, uric acid and urates abounding, and the urea increased even to double the normal amount.

---

[7] Some Problems in Metabolism Occurring in Patients with Certain Diseases of the Skin, Jour. Cutan. Dis., April, 1911.

Acting on these indications we find psoriasis always benefited by alkaline diuretics, and a strict vegetarian diet, involving a restriction as to the intake of nitrogenous elements, shows alike in the urine, while it produces its beneficial effects on the skin. It is interesting to observe, however, that often for quite a period after entering on a vegetarian diet, the urine may still show evidence of excessive uric acid elimination, thus supporting the view which has sometimes been criticized, that there is at times a retention in the system of waste nitrogenous products which operate harmfully, and which the blood takes up much more readily, in proper combination, when relief is afforded by a non-nitrogenous diet. This is not the place to enter into a further consideration of the chemistry of the body, or to trace where the error of metabolism lies; but it certainly has to do with the functioning of many organs and parts of the system, and medical acumen and skill are required to discover and rectify the faulty actions involved.

Therefore, while a strictly vegetarian diet is strongly advocated in psoriasis, and while under certain conditions it is quite possible for the lesions to disappear under its influence alone, with no other treatment, internal or external, it is to be clearly understood that this is not the only element of treatment to be considered, although undoubtedly the most important one. To obtain the best results there is need of constant medical supervision in order to secure the best working of the economy in all directions, and proper internal and external medication can accomplish very much more in connection with an absolutely vegetarian diet than without it. It is, of course, impossible here to enter into any details regarding these matters.

A few words may be added in regard to the practical working out of the problem of vegetarian diet. When it is first explained that this diet means the absolute exclusion of all kinds of meat, poultry, fish, eggs, etc., and living only on the products of the ground, many patients hesitate and ask, "Well then, what can I eat?" So that it will often require some little patience and thought to aid them in securing a properly nourishing dietary; and it requires some watching to keep them strictly up to it. But with help they soon learn to manage successfully, and I have many who would not return to a mixed diet under any consideration. Many speak of their unusual well-being, and feel most grateful for the improvement in general health and vigor.

There are some articles from the vegetable kingdom, however, that have to be guarded against. Alcohol in any form, even the lightest beer, is prejudicial, and in some instances I have found better results when I excluded coffee, chocolate and cocoa, allowing only weak tea, and water in abundance. Butter is the only non-vegetarian substance which is allowed, unless it be possibly a little very fat bacon, occasionally. I do not allow milk to be used as a beverage, or on cereals, which should be eaten with butter and salt. Care must be taken against indulgence in sweets, and I commonly cut off pastry. Nuts, if well chewed, seem to act well, but much acid fruit seems sometimes to interfere with the treatment; vinegar on salad is harmless.

The question is asked about the ultimate results: "Is psoriasis curable with a perfectly carried out vegetarian diet, and proper other treatment?" This is a difficult question to answer very positively, because of the well-known character of the disease and the uncertainty of patients, as to their again consulting the same physician if there should be a relapse. But from my watching this treatment for more than twenty years, and from my more special study of the subject the last two years, I believe that a very considerable proportion of patients can be cured and remain well under a strict diet.

On study of the records of the cases here analyzed, there were eighty-one who were recorded as strictly faithful to diet, and twenty-four who were fairly faithful. There were thirty-two in whom the eruption was recorded as gone, and sixty in whom it was improved, and only sixteen in whom it was recorded as not improved, but of these, thirteen were not faithful to diet. Some of these patients have been seen later, for one reason and another, and remain free from eruption, but there are quite a number who return now and again, after a period of unfaithfulness to diet, with a greater or less amount of eruption.

Finally, it may be said without equivocation that the results of this plan of treatment, as watched by my several associates in years past and myself, and by physicians in consultation, and by very many most intelligent patients in private practice, far exceed anything which had been previously secured by the best of treatment at the hands often of the best men in the profession.

531 Madison Avenue.

ABSTRACT OF DISCUSSION

Dr. D. W. Montgomery, San Francisco: The etiology of psoriasis has always been a riddle to dermatologists, and no theory is satisfying and no line of treatment gives absolutely satisfactory results. Even if it be as Dr. Bulkley maintains, a nutritional disease, yet it certainly is not a disease of degeneration, as the people who have psoriasis are usually the strongest and healthiest of a community. It is rare to find a weakly, sickly individual with this disease. These people are strong and healthy, and have a beautiful white skin and muscles like iron. I knew a man in San Francisco who had psoriasis and whose eruption cleared up every time he went fishing. A ready explanation would be that his nutrition improved with the exercise and fresh air. I also remember that the late Dr. J. Nevins Hyde reported the case of a patient whose eruption cleared up on living naked in the strong sunlight of Arizona. This disappearance of the eruption under the influence of sunlight is interesting, because psoriasis rarely occurs on the exposed skin of the face and hands, and patches of psoriasis may be temporarily cleared up under *x*-rays. Whether light acts in psoriasis as light or as a nutritional agent is not known.

I have never tried Dr. Bulkley's diet, but I should think it a very difficult one to enforce. It is doubtful if a man could feel strong and well on an entirely nitrogen-free diet. It is my habit, however, to regulate the diet of these patients with the view that the eruption is connected with poisons of fermentation generated in the alimentary canal, but in regulating the diet I do not deny them meat.

Dr. Bulkley's observation in regard to the rarity of psoriasis in rice-eating countries is very interesting. I have long had my eye on rice as a most excellent starch. The Chinese have for ages lived, just on the edge of subsistence, with rice as their main food, and yet are a strong vital race. I do not think they could have done this on such a starch as potato. Martinet asserts that rice contains an antiseptic principle, and that under its influence indican disappears from the urine. There may be some connection between this antiseptic principle of rice, and the rarity of psoriasis among rice-eating peoples.

The darker races are very insusceptible to psoriasis. Psoriasis is almost never seen in the negro, although the negro is a heavy meat-eater. The freedom of the negro from psoriasis may be dependent on the peculiar insensitiveness of his skin to light. In fact, the freedom of all the heavily pigmented peoples may rather be due to their peculiar reaction to light than to their lack of carnivorous food.

DR. J. S. TREWHELLA, Los Angeles: I would say from personal experience that a restricted nitrogenous diet has been beneficial to me. I would prefer to have psoriasis and have meats than be restricted.

DR. LAWRENCE LITCHFIELD, Pittsburgh: Is it not possible that by adding purin-free articles to his nitrogenous diet, Dr. Bulkley might get good results? It may be that the purin metabolism is at fault.

DR. L. DUNCAN BULKLEY, New York: I have not followed out the point made by Dr. Litchfield, but will take it up and report perhaps next year. In regard to living on that diet and keeping healthy, I have kept patients for weeks on rice, bread, butter and water, with only good effects. Indican disappears from the urine under this diet. If you see the Japanese and Chinese at work you will see what wonders they can do on rice. I have had people suffering from psoriasis for ten or twenty years in whom the eruption has faded away under a vegetarian diet alone. To show how rare psoriasis is among the dark-skinned races, who live on cereals, my son, who is a medical missionary in Siam, sent me recently a photograph of about the first patient with psoriasis that he had seen in six years there.

A REPORT ON THE USE OF CACODYLATE OF SODIUM IN FOUR CASES OF PELLAGRA

J. O. ELROD, M.D.
FORSYTH, GA.

Because pellagra is a new disease in this section of the country, because the number of its victims is increasing rapidly, and because the treatment has been so varied with so small a percentage of success, I am making a report of four cases. So far as I can gather from journals, or any publication on this disease, the profession has not decided what the cause of pellagra is; almost every one suggests a different cause. As we all like to know the cause of any trouble before we begin our treatment, it seems to me that our greatest work is to find out the cause of this disease, but while we are doing this we must not sit still and do nothing for the patient.

CASE 1.—*History.*—Mrs. S., aged 23, white, whose husband was murdered in December, 1909, had two children, one born November, 1905, the other, December, 1907. She said that erythema of the hands, and spots on the dorsa of the feet had first appeared during the spring of 1905 and 1906; these attacks she thought were eczema, and they passed off after a few months with local treatment. Erythema did not reappear until the spring of 1909, when it appeared on the hands, feet and elbows; again it disappeared with local treatment. During these times the patient was in a very run-down state of health, but though hardly able to be up, continued to do her housework. During the spring of 1910, there was some appearance of the erythema, but not very much. During the first days of January, 1911, the patient became so debilitated that she was not able to be up, the eruption began to appear on her hands, feet, elbows and a few places on her face. At this time she called in a physician, and after several weeks of treatment she continued to grow worse. February 12, she and her mother, with whom she was living, requested the attending physician to call in another physician with him. This he refused to do and dismissed the case. February 13, I was called to see her, and on examination I found her with a circulation of 110, temperature 101 F., very weak, not able to turn herself in bed, and very nervous. I found an eruption extending from the tips of her fingers along the backs of the hands up the forearm to within three inches of elbow, also spots on the point of the elbow, on the neck, around the alæ of the nose, on the dorsa of the feet, on the knees, and for several inches around the anus. The character of the eruption was scaly, and pigmented around the edges; under these scales was a secretion of serum. All of the eruptions were very red and angry looking. The mucous membrane of the mouth showed a thick, and spongy appearance. The gums were thick and spongy, and would bleed from the least touch. The tongue was red and smooth, and had a velvety touch.

The patient had very little appetite, some nausea, vomiting, diarrhea, with from twenty to thirty bowel movements in twenty-four hours. The irritated condition of the mucous membrane of the mouth seemed to extend through the entire alimentary canal. She suffered with general muscular aching most of the time, slept well during most of the night, but very little during the day. The loss of flesh was very marked. The patient was extremely nervous, and at times had hallucinations and crying spells. For some time she suffered with diplopia; aside from this the eyes seemed to be all right. She had not menstruated for about twelve months.

Treatment.—On February 13, I gave the patient two ounces of castor oil, to clear out the alimentary tract; after this I gave her a combination of bismuth subnitrate and camphorated opium put up in lactated pepsin elixir, also a hypodermic injection of morphin sulphate, 1/4 grain several times each day. For the eruption I tried an ointment of phenol (carbolic acid) and zinc oxid. For the mouth I gave an alkaline mouth-wash; for the weakened condition and rapid heart I gave strychnin nitrate, 1/30 grain, every four hours; all of these things I did up to February 24, and none of them seemed to do any good, as the patient gradually grew worse. On the above date, Dr. G. L. Alexander saw her with me and suggested that I give her cacodylate of sodium as an experiment, as it could do her no harm, and she did not look as if she could live but a few days. I gave her a hypodermic injection on that day, of 3 gr. of the sterilized solution of cacodylate of sodium. On the following day, the patient appeared to be very much worse, having all kinds of hallucinations, and talking incessantly for several hours. At this time her pulse was very weak and rapid, and she looked as if every moment would be her last. I gave her at this time a hypodermic injection of digitalin, nitroglycerin and strychnin, and kept her as quiet as I could with an occasional dose of morphin. February 26, she was very much improved. On account of her weakened heart action from the depression of the day before, I continued the digitalin, nitroglycerin and strychnin, giving it every four hours. I kept up the alkaline mouth-wash that I had given her in the beginning, and began using carron oil to soften the scaly eruption on different parts of the body. I continued the cacodylate of sodium injections, giving them every three days. After I had given her ten injections, the eruption had all disappeared and the parts showed only the appearance of new skin. The tongue had lost some of this redness, and the mucous membranes of the mouth had improved a great deal. The bowels began to check up after the third injection, and after the fifth, they did not move more than twice a day. The appetite began improving after the first injection, and temperature and pulse gradually went back to normal. As her appetite improved, the patient began gaining strength and flesh, and by March 1, she was beginning to sit up, and since that time she has menstruated. At the present writing, I give her the injection of sodium only once a week. This patient thinks she is cured, since she has no apparent symptoms, is able to visit her neighbors and to do most of her housework.

CASE 2.—*History.*—Mrs. D., aged 22, has no children. For the past two years she has experienced a general physical decline. She has been consulting me during this time, and I could never find anything organically wrong with her, though she continued to lose weight and strength. During the past spring I began to notice that her tongue was spongy, red and very smooth, and would bleed from very little irritation. I did not see her very often, and May 16 she came to me complaining that her hands had been blistered by the sun. On questioning her, I found that she had considerable irritation of the feet. On examination I found the back of her hands and several inches of the forearm in a blistered condition, as if done by the sun. The edges of the blistered parts were very brown. From the above symptoms I made a diagnosis of pellagra, and began giving her every three days hypodermic injections of 3 gr. of the sterilized solution of cacodylate of sodium. The last injection I gave her was on June 8, at which time her condition was very much improved, and she had gained her strength so rapidly that she told me that she was well and did not believe she needed any more medicine, claiming that she felt better than she had felt in two years. All of her symptoms have entirely disappeared, and apparently she is well.

Case 3.—*History.*—Mrs. R., aged 33, has had five children, the youngest of whom is two years old. While under my charge the past two years, she gradually lost flesh and strength, and I could find nothing organically wrong with her. I gave her tonics, digestants and everything I knew that might apply to the case, and failed to help her.

May 25 she called me in to see her; at this time I had not seen her for some weeks. She showed me a scaly eruption, which was all over her face and hands, and which did not look like any I had ever seen in cases of pellagra. Her tongue was red, and velvety to the touch; the gums were red and spongy and would bleed from very little irritation; the temperature and circulation were normal, the bowels were constipated, the feet burned and ached all the time. As the eruption in this case was different from any I had seen, I guardedly made my diagnosis pellagra, and began giving an injection of cacodylate of sodium every three days, also 2-dram doses, three times a day of elixir of iron, quinin and strychnin (U. S. P.). For her constipation I am giving her 1-dram doses of arom. fluidextract of cascara sagrada once a day. The patient has improved gradually since the beginning of the above treatment and the eruption has entirely disappeared.

Case 4.—*History.*—Mr. W., aged 49, farmer, past history negative. May 27, he came to me with back of hands and forearm half way to elbows looking as if they had been blistered by the sun, and told me he had burned his hands.

I had not seen this man for some time and I was very much surprised on weighing him to find that he had lost 32 pounds in the past six months. He told me he was troubled with indigestion and constipation all the time, that he had no appetite, and that he had lost his strength until he was hardly able to work. I found his mouth and tongue in the same condition as reported in the other cases. I began giving him a hypodermic injection of 3 gr. of the sterilized solution of cacodylate of sodium every three days, and in two weeks he had gained one pound, with no other treatment except the sodium.

REMARKS

Since we know very little as to the cause of this disease, I shall give some details as to the origin of these cases.

The patient mentioned in Case 1 lived nine miles from Forsyth during the first four years she had her first symptoms of the disease. Just one quarter of a mile from her home lived a man, 73 years of age, a patient of mine, who died of pellagra two years ago. This man was the father of Patient 4; before the father's death, the two lived in the house together. For the past year Patient 4 has lived in the house where Patient 1 had lived for four years. Near this house there is a small stream of water and a great deal of marshy land.

The mother-in-law of Patient 2 died of pellagra in November, 1906. I did not recognize it as pellagra at that time, but since knowing something of the disease, I realize that is what she died of. Patient 2 did not live near her mother-in-law at the time of the latter's death, but for the past three years she has lived within three hundred yards of the house in which her mother-in-law died, and has been on the decline all the time. Near this place is a stream of water with marshes around it.

The patient mentioned in Case 3 lives within one-eighth of a mile of a running stream of water; there are not very many marshes adjoining this stream.

Since reading an article by Dr. A. Cacini of New York,[1] also an abstract of an article of Dr. L. W. Sambon,[2] I have recalled that all of the patients afflicted with pellagra that I have ever seen have lived near a stream of water, and in the rural district! For these reasons I am beginning to believe the theory of these writers as to the cause of pellagra. From the cases I have seen, I believe it to be an insect-borne disease; I do not believe that the corn-bread theory is worth anything, since a good percentage of these patients have never eaten corn-bread. Patients 1 and 4 in this report have never eaten corn-bread to any extent. I believe that Patient 1 had the typhoid pellagra of which Dr. Cacini speaks. I also believe that her recovery would have been more rapid had I given her the injections of sodium more frequently.

THE PATHOLOGY OF JOINT TUBERCULOSIS*

LEONARD W. ELY, M.D.
DENVER

It may seem somewhat bold for an orthopedic surgeon to address the members of an august body like this on a matter pertaining to their own specialty, and were there anything like a unanimity among you, I should hesitate.

That the greatest confusion exists as to the pathology of joint tuberculosis, one can easily find by consulting a few text-books and by reading a few articles on the subject. This confusion, of course, is reflected in all the aspects of the disease, and until the exact pathology is laid down in full and comprehensive terms, it is futile to look for any scientific treatment of the disease. In other words, although the cause of the disease has been known for many years, the failure of the pathologist to place the pathology on a sound footing, is responsible for the chaos in the whole subject of joint tuberculosis.

In self-defense, then, I entered on this work, to see what I could find out for myself, and I shall here attempt to set forth as briefly as possible some of my findings. My material consists of about eighty specimens, supplied by various men. Most of the specimens consist of resected joints, some of amputated extremities, and a few of clippings from joints that had been opened for one purpose or another.

The first question to be discussed is, where joint tuberculosis starts and what tissues it affects. It starts in the marrow of the spongy bone ends or in the cellular synovia, and as long as it remains uncomplicated, it is confined to one of these two tissues or to them both. The bone itself, the cartilage and the ligament are damaged simply by interference with their nutrition, and may be said to play a purely passive part in the disease. The tendency in recent years in America has been to regard all joint tuberculosis as of bony origin, and the theory has the attraction of simplicity, but, starting out myself with this view, I have been compelled to abandon it.

A study of our specimens and of the histories of the patients from whom they were taken convinces me that primary synovial disease not only occurs but is quite frequent in adults. In children, disease of the bone-marrow predominates. The reason for this we shall presently see. Synovial tissue is distinctly vulnerable to tuberculosis. It is classed among structures of the lymphatic system. We find the disease rather frequently in tendon sheaths.

The next point is, why tuberculosis occurs in the extremities of the long bones and not in the shafts. As you know, various explanations have been advanced for this phenomenon, but as you also know, none of them has ever been accepted as adequate. Liability to injury has been said to be responsible, but trauma is no cause of tuberculosis, and if we injured a muscle or a ligament, or if we fractured a bone, we should not expect tuberculosis to ensue, and we must not forget that the tissues of a joint are adapted generally to the traumata to which they are exposed. Some say that the vulnerability is due to the arrangement of the blood-vessels, to the lack of anastomosis in the end arteries of the epiphyses in childhood, but the anastomosis is present in adults, and the lack of anastomosis in the blood-vessels of the brain, for instance, does not predispose to cerebral tuberculosis. To congestion has been ascribed a causal rôle, but congestion has been advanced as a means of curing the disease.

About a year ago, I proposed an explanation which appeared to me quite adequate, and I see no reason as yet to change my opinion. Bone tuberculosis is simply a question of red or lymphoid marrow. Wherever in bone we find lymphoid marrow, there we find the bone vulnerable to tuberculosis, and where we do not find it, there we do not find unmixed tuberculosis. This might be regarded as a coincidence, but the argument is reinforced by the fact that after a resection of a joint, the knee for instance, if bony union and primary healing be attained, the structure of the bone at that site changes from spongy to dense, and the disease disappears, whether or not we have removed all the infected tissue. There is no difference between dense and spongy bone except the arrangement of the lamellæ, the amount of bone, and the quality of the marrow, and we have already seen that the bone itself is never affected.

In the spongy bone we find the red or cellular, or lymphoid marrow, and where we find lymphoid tissue there tuberculosis can get a foothold. There is more red marrow in the bones of children than in those of adults. Hence, bone tuberculosis is more frequent in the former than in the latter. Primary tuberculosis of the shafts of the long bones has been described, but almost always, or invariably, of the shafts of children's bones alone, and red marrow exists in them. Joint tuberculosis is rare in children under 1 year of age. Their bone ends are composed almost exclusively of cartilage, and Rovsing has said that the joint tuberculosis of infants was probably always purely synovial. The yellow marrow appears to be invulnerable, but if a secondary infection be added then the disease may spread here also, as well as to other tissues also previously immune.

When we find a tissue subject to tuberculosis in a certain region and find further that when this tissue disappears, the disease dies out, we are certainly justified in regarding these facts as having some sort of a causal relation to the disease.

König has attached great importance to the precipitation of fibrin from the exudate in the joint. By means of this fibrin he has asserted that the cartilage is eroded and destroyed from the joint side, and that the synovia is infected from the exudate. In fact, he seems to assign to the exudate a very important part in the spread of the disease. I am forced to the conclusion that his examination of joints must have been almost exclusively macroscopic. I assign to the exudate a minor rôle and regard it more or less as a mere symptom, and quite unimportant in the pathology. I think the synovia is invaded by the primary tubercle in its substance, or else by a spread of the disease from the bone, where the synovia is attached at the margin of the cartilage.

The "layers of fibrin" which König describes on the cartilage, I think, are simply the evidence of the fibrillation of the superficial layers of the cartilage, caused by the interference with its nutrition and by the immobilization of the joint. The fibrillation can be plainly seen in sections. The cartilage may be perfectly smooth in joints which have been for years the seat of a tuberculous exudate. I have the joints to prove this. On the other hand, the fibrillation (or "layers of fibrin") may not be in evidence in a cartilage that has been lifted off the subjacent bone. If this bone is in good condition, that is, if the nutrition of the cartilage has not been involved, the cartilage will usually be found in pretty good condition. I believe that it is never damaged except from below.

The subject of rice bodies has also attracted some attention. Two theories have been held in regard to them: that they were the result of the precipitation of fibrin, or of a degenerative process. I consider them as the product of an effective attempt at repair, as the walling off of the tuberculous granulations and subsequent condensation and shrinking. One of our specimens (a knee-joint) contained a collection of them in a fibrous capsule. I think that the slide of this specimen is unique. The joint also contained a small encapsulated hematoma. Both are rare—one may be the later stage of the other.

PYOGENIC MEMBRANES

In almost all text-books tuberculous abscesses and sinuses are described as being lined by a pyogenic membrane; that is, by a wall of granulation tissue, filled with tubercles. The walls of these abscesses or sinuses, *if they are not infected secondarily with pus germs*, are composed of the necrotic tissue of the structures in which they lie. If the tissue is vulnerable to pure tuberculosis, then tubercles may be found in the walls of the abscesses or sinuses, otherwise they will not be found there. In a cross-section of the walls of a secondarily infected tuberculous sinus, tubercles will be seen, in one not secondarily infected they will not be seen. The importance of this fact to the subject of treatment is at once obvious.

What is the result of an old healed tuberculosis of a joint or of a tuberculosis thought to be healed? One hears the term "ankylosis" used somewhat at random, and more or less vaguely. In children, one may occasionally get a bony ankylosis, but only after a secondary infection. In not one of our specimens of adult tubercul joints was a bony ankylosis present. I believe th never occurs except after a resection.

As to healing, what may one expect? In a child, thing from good function and a practically c cure, up to a bony ankylosis. In an adult, I beli that if the bone be involved, painless and useful function in that joint is at an end forever, and permanent healing under conservative treatment is very doubtful. In one of our resected adult knees, we found an old healed tubercle in the bone, just beneath the cartilage, buttressed off with fibrous tissue and bony trabeculæ, and yet, the disease must have broken out afresh or the joint would not have been excised. In another case, ankle, we found an old tubercle buried in fibrous sions. In some of our cases, the history runs back for years.

Finally, let me mention the unreliability of the examination of a clipping from a joint for diagnosis. Tuberculosis *may exist in one part of the synovia and not in* another. The reports of different laboratories from sections of the one joint will often differ. If tuberculous tissue be found, the report, of course, is final; if not, the joint may still be tuberculous.

Thorough mastery of the pathology of joint tuberculosis by the profession would soon put an end to the diverse, and sometimes fantastic, treatment of the disease, which now prevails.

TONSIL INSTRUMENTS

RICHARD J. TIVNEN, M.D.
Instructor in Ophthalmology and Otology, Northwestern University Medical School; Member of Consulting Staff of the Cook County Hospital
CHICAGO

TONSIL HEMOSTAT

During a tonsil operation, it frequently occurs that after one tonsil has been removed a considerable period of waiting is necessary to control the resulting hemorrhage before the operator obtains a clear operative field and may, *without annoyance from the hemorrhage,* proceed to the removal of the remaining tonsil. In such cases my tonsil hemostat (Fig. 1) has proved efficient.

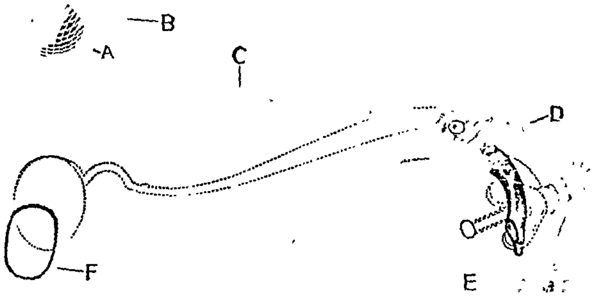

Fig. 1.—Tivnen's tonsil hemostat. A, serrated aluminum tonsil pressure bulb, oval in form to conform to tonsillar fossa. B, curve, which overrides the anterior pillar. C, arm, curved to rest, external to the teeth, between the alveolar process and the cheek. D, portion projecting from mouth. E, thumb-screw and swinging arm lock for securing instrument when closed and applied. F, the external fenestrated counter-pressure plate. The unbroken heavy lines indicate instrument when open. The dotted lines indicate its appearance when closed.

It arrests the hemorrhage promptly, eliminates the delay usually incident to its control, secures a clear operative field and thereby shortens the period of anesthesia, the time of operation and minimizes greatly the danger of subsequent hemorrhage. The special *application of this hemostat is for the control of hemorrhage during* the operation. It may be used, however, equally well for postoperative tonsillar hemorrhage.

Its application is expeditious and simple; it can be used for either tonsil without change or adjustment and being constructed entirely of metal, may be boiled without injury.

The clamping arms of the instrument are thin, light in weight, and, *when in position,* the inner arm and pressure bulb adapt themselves snugly to the tonsillar fossa and anterior pillar; beyond the pillar, the arm is so curved as to rest between the alveolar process and the cheek; while the portion of arm and lock protruding from the mouth is short, curved abruptly to the outer side, and entirely out of the way of the operator.

The field of operation is not in the least obstructed by its use and neither the subsequent introduction and manipulation of the necessary instruments for the removal of the remaining tonsil nor the technic of the operator need be curtailed, modified or embarrassed by its presence.

In using the instrument, I have found it of advantage to cover the oval bulb with three or four layers of sterile gauze, the ends of which are first trimmed short so they will not project into the operative field, then gathered together and secured just over the base of the bulb by an ordinary rubber band, previously sterilized. This covering is moistened with a 1-to-1,000 solution of epinephrin (adrenalin chlorid).

A pad of gauze is also placed just behind the angle of the jaw to protect it from the slight amount of pressure exerted at this point by the external counter device of the instrument.

The advantages of the instrument summarized are:

1. It arrests tonsillar hemorrhage promptly and is available for either operative or postoperative hemorrhage.

2. It can be quickly applied to either tonsil, without change or adjustment, and when in use does not in the least obstruct the operative field.

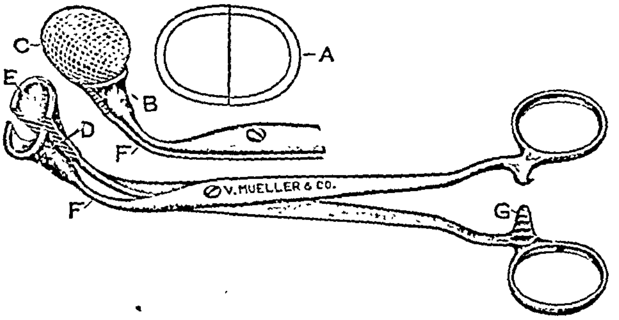

Fig. 2.—Tivnen's tonsil sponge forceps. A, outline of sponge-cup. B, base of sponge-cup. C, sponge in position. D, instrument opened to show serrated portion at inner side of cup base for retaining ends of sponge. E, receptacle for sponge. F, showing angle of sponge-cup to the handle. G, lock.

3. It is simple in construction, light in weight and being entirely of metal may be sterilized by boiling without injury.

4. The amount of pressure necessary to exert in controlling the hemorrhage is slight and when the pressure applied is judiciously *graduated and not unnecessarily* prolonged, the tissues are not traumatized and the patient is not subjected to additional hazard by its use.

5. By securing a clear operative field, it conduces materially to the carrying out of a satisfactory technic and surgical thoroughness, shortens the anesthesia and operative period, eliminates the hazard and annoyance of operative hemorrhage and minimizes the danger of subsequent hemorrhage.

TONSIL SPONGE FORCEPS

A satisfactory tonsil sponge forceps should be light in weight, simple in design, easily operated, carry securely a sponge of sufficient size and form to serve its purpose adequately and so constructed as to adapt itself readily to the oral cavity and tonsillar region.

My tonsil sponge forceps (Fig. 2) was designed to meet these requirements.

The instrument is provided with a lock to hold the sponge securely; the sponge receptacle is cup-shaped, oval in form to correspond to the general contour of the tonsil and tonsillar fossa; the "cup" in which the sponge rests is sufficiently large to accommodate a sponge of proper size; the edge or "flange" of the cup is overlapped by the sponge, thus presenting a smooth, cushioned surface, which minimizes the trauma to the tissues to which it is applied and in addition provides an even, firm resistance of a solid oval sponge-body, which exerts firm and evenly distributed pressure throughout every area with which is comes in contact.

The two halves of the sponge cup are serrated at their base to engage firmly the base of the sponge, which is inserted between them; the cup itself is placed at a slight angle to the carrying arm of the instrument to permit the operator an unobstructed view of the tonsillar area when applied and to promote facility of application to the depths of the tonsillar fossa. The sponges for the instrument are prepared by taking a small square of gauze, filling with cotton to the required size, and then gathering the ends of the gauze together over the cotton filling—much as a pouch is made.

The gathered ends of the gauze are twisted together and are then easily inserted between the open halves of the cup, which is closed and locked. Before operation, a sufficient number of such sponges are thus prepared and sterilized. From four to six sponge forceps should be at hand for the operation and during the operation the assistant is entrusted with the arming and disarming of the instrument.

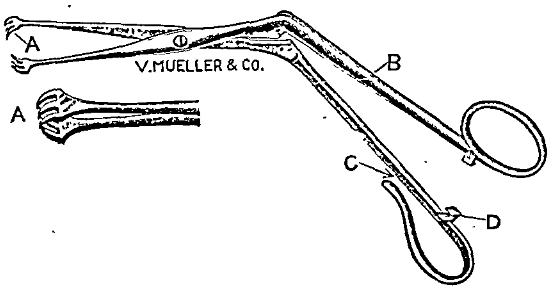

Fig. 3.—Tivnen's tonsil-grasping forceps. A, tonsil grasping portion. B, showing angle of handle to grasping arm. C, opening in finger ring for introduction of snare. D, lock.

ADENOID HEMOSTAT

The amount of blood lost in the removal of adenoids is usually considerable.

While the hemorrhage is not ordinarily considered of serious moment, occasionally, however, it is accompanied or followed by serious consequences to the patient. It is therefore the manifest duty of the operator to safeguard his patient in every possible way and to eliminate every factor which may endanger the patient's life or prolong his period of invalidism.

Viewed from this standpoint, the control of hemorrhage incident to the adenoid operation becomes a matter of importance and merits thoughtful consideration.

My adenoid hemostat is designed for the control of hemorrhage during or following adenoid operation.

In design and construction, this instrument differs in only one essential particular from the tonsil sponge forceps above described. In the adenoid hemostat, the sponge-cup is placed at nearly right angles to the carrying arm in order to accommodate itself easily to the nasopharynx, the angle of the sponge-cup to the handle, marked F in Figure 2, approaching more nearly a right angle in the adenoid hemostat.

The sponge used is previously prepared and its size is regulated from an estimate of the size of the patient's nasopharyngeal space.

After removal of the adenoid, the sponge is moistened in epinephrin (adrenalin chlorid) solution (1 to 1,000) and is quickly but gently applied to the nasopharynx, being introduced in the same manner as the adenoid curet. It is then pressed firmly against the vault of the pharynx and retained in this position until the hemorrhage has ceased, and is then slowly and gently withdrawn.

TONSIL-GRASPING FORCEPS

The advantages of this instrument (Fig. 3) are:

1. It is thin, light in weight and delicate in construction, thus permitting facility of operation and an unobstructed view of the tonsil and tonsil area.

2. The grasping portion is curved to adapt itself to the tonsil contour; the teeth, three in number, are edged, curved, spaced and approximate snugly to engage the tonsil easily and securely. This arrangement is of especial advantage in dealing with the so-called "submerged" variety of tonsil.

3. The handle of the instrument, being nearly at right angles to the grasping portion, the hand of the operator is situated out of the line of vision and thus presents an unobstructed view of the field of operation at all times.

4. When the tonsil is once engaged the instrument is locked, and the tonsil remains secured until removed.

5. The snare is applied without releasing the tonsil, by entering the loop at the opening in the finger ring, sliding it over the instrument down to and over the tonsil.

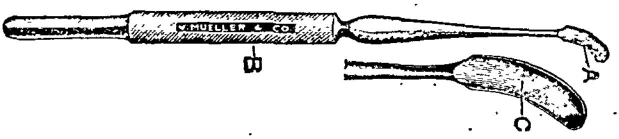

Fig. 4.—Tivnen's tonsil pillar separator. A, cutting edge of blade. B, handle. C, showing oval form of blade from side to side.

TONSIL PILLAR SEPARATOR

The advantages of this instrument (Fig. 4) are:

1. It is of sufficient weight to impart a comfortable sense of resistance and balance to the operator's hand.

2. The length of the handle enables the operator to perform the necessary manipulation without obstructing the view.

3. The handle is round to permit rotation of the instrument and is serrated throughout so that it may be held firmly and securely.

4. The blade is placed almost at right angles to the handle; it is slightly oval from side to side to conform to the tonsil contour and is thinned and rounded at the point; and the cutting edge may be made sharp or dull.

32 North State Street.

THE INFLUENCE OF THE THYROID AND PARATHYROID GLANDS ON THE HEALING OF FRACTURES *

R. L. THOMPSON, M.D., and J. L. SWARTS, M.D.
ST. LOUIS

Since skeletal disturbances are so striking a feature in athyreosis, it is easy to conceive that a fractured bone in an animal deprived of thyroid gland would suffer delay in healing. That this is true seemed to be proved by Steinlen in 1900, who, using young rabbits, observed a definite delay in the time of fracture healing in animal operated on. The same was explained as a result of the delay in callus formation and lack of calcium deposit, so that there was a persistence of uncalcified cartilage beyond the period when normal animals showed unmovable solid bone.

While the results of Steinlen seemed conclusive, they were attacked by Pezzolini (1903) who asserted that it was not the thyroid removal, but the general cachexia of the animal that retarded healing and regeneration.

Still more recently (1909) Canal, and also Morel, basing their assumptions on the theory of the relation of the parathyroid glands to calcium metabolism, found that fractures healed more slowly after complete parathyroid removal than in control animals. Jovane and Vaglio, however, dispute their results.

In our experiments we have attempted to observe the results of both thyroid and parathyroid removal on the time of fracture healing as well as a few attempts at the production of thyroid hypertrophy during the course of fracture healing. This work we consider incomplete, for, although over fifty dogs were used, so many factors enter into the cause of delay in fracture healing that much more work must be done before any definite conclusion can be drawn. Among the points to be considered are age, size and individual susceptibility in the different animals. Considerable variation (even to absolute lack of union) can be obtained by variations of the technic with which fractures are performed. It is needless to say, also, that slight inexactness in the apposition of the fractured fragments may give considerable differences in the size of the callus, and that the animal must be carefully watched throughout the whole course of the recovery to prevent injuries that might retard healing.

Aside from all this, the greatest difficulty which we encountered in this work was the complete removal of all thyroid tissue. Anyone who has worked with dogs knows how infrequently myxedema symptoms occur in these animals, even when all visible thyroid tissue is removed. We were able to account for this by the finding of pericardial thyroid tissue in 80 per cent. of our animals, as we have described elsewhere.

Taking all these varying factors into account, then, we give the following results of our work. The malar bone was selected in most instances for fracture. In some cases the femur was fractured. Most of the experiments were following complete thyroidectomy. One series was following mass ligation of the parathyroid glandules, since it has been shown that these organs may be gradually destroyed in this way without the sudden tetanic death which follows complete parathyroidectomy.

After the removal of all visible thyroid tissue and the attempt to leave behind at least two parathyroid glandules to prevent tetany, the animal was left for from two to eight months and watched for the development of signs of myxedema. Out of twenty-one animals thus operated on, only two developed distinct myxedema, as was shown by the increase in size, the thickening of the skin and subcutaneous tissue, and the falling out of hair. (Several animals in this series died from sepsis and tetania parathyropriva.)

By experiments on control animals, it was found that healing of the malar bone, when chiseled through and the fragments carefully approximated and covered with periosteum, showed practically complete healing in about forty days. While a number of animals were examined at shorter and longer intervals, it was decided to use the myxedematous animals for study of the bone thirty days after the fracture. Several of the thyroidectomized animals not showing myxedema were also examined thirty days after fracture, and normal animals with thirty-day-fractured malar also were used for control.

While differences were found in the amount of union that had taken place, these differences were greatest between different animals in the control series and not between the control animals and the thyroidectomized animals. For instance, there were two cases of lack of union and both were in control animals. In general, in the control animals and in the thyroidectomized animals, both with and without myxedema, practically identical pictures were obtained.

Macroscopically, the fractures were well united with little or no visible callus. When the bone was removed, fibrous union could be seen, and the section showed fibrous tissue between the bone fragments.

Microscopically, considerable difference is to be noted in individual animals in the amount of connective tissue between the bone fragments. This may vary from a hardly discernible line to the width of two-thirds of a low-power microscopic field. When the bone is fixed in Zenker's fluid and stained with Mallory's anilin-blue connective tissue stain, the calcium content of the bone usually takes a distinct brown (or brownish yellow) color. With this stain, no lack of ossification is to be observed in the thyroidectomized animals that is not shown in the control animals.

Following the negative results obtained in this series of experiments, a method was sought whereby the influence of the parathyroid glandules on the healing of fractures might, in some measure, be ascertained. Canal states:

> In my experiments on animals completely parathyroidectomized, I have observed that there is a delay in the healing of the fracture when compared with the animal of control under the identical condition of feeding and living. However, in experiments on animals partly parathyroidectomized, I have found that there is not the least delay in the healing.

While we do not know how Canal's results were obtained, one of us has shown in a previous article that dogs may be kept alive for some time even after complete destruction of the parathyroids if this is brought about by gradual destruction of the glands by mass ligation. The animal finally dies, but from cachexia instead of tetany, sometimes remaining in a state of torpor for several weeks.

Our experiments were carried out on only six animals in this series. The femur was the bone selected for fracture. Control animals show complete repair in one month after fracture of this bone. No comparative results that we care to record were obtained with the animals operated on. The extreme cachexia which these animals suffer, when successful operative results are obtained, makes comparison with normal animals impossible.

---

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

* From the Department of Pathology, St. Louis University School of Medicine.

In conclusion, we find that, in the limited amount of material which we have studied, the lack of thyroid tissue has no influence on the healing of fractures of the malar bone of the dog. We see at present no exact method of studying the results of complete parathyroid removal on the healing of fractures.

A TUBULAR SOFT RUBBER NASAL SPLINT THROUGH WHICH THE PATIENT CAN BREATHE [*]

MARK D. STEVENSON, M.D.
AKRON, OHIO

The nasal cavity is narrow, quite long anteroposteriorly and varies in height. Each cavity has two openings, one in front and one behind, of about the same size and nearly on the same plane. To prevent escape of blood from either side of the nose and thus to stop a nasal hemorrhage, it is only necessary to obstruct the two nasal outlets. This can be accomplished by various means, several of which I described in a former paper.[1] The 3-inch-long and ½-inch-wide solid cotton tampons therein described, which swell on absorption of moisture, effectually prevent hemorrhage and are sufficiently flexible to adjust themselves to the more or less tortuous nasal cavity, but nasal breathing and drainage are entirely prevented.

The hard rubber and metal nasal splints now on the market are open to the following objections:

1. They are not flexible and unduly press against certain parts of the nasal structures.
2. Their ends vary too much in size. The smaller end permits so little drainage that the secretions dry and form crusts before being discharged from the large outer end.
3. The smaller end is usually too nearly circular in shape, the nasal cavity is narrow but not vertically shallow.
4. A short splint or tampon tends to slip out of the anterior naris. The posterior end, usually near the part operated on, is pressed upward and outward by the congested tissues until the splint or tampon readily slips downward out of the nostril. This defeats the purpose of the splint, requires the surgeon's attention, or its replacement may be effected by dirty fingers with consequent danger of infection.
5. Only the anterior naris and the front part of the nose can be influenced by these short splints.

The splint or tampon which I am presenting to the Section has the following advantages:

1. It is sufficiently strong but soft and flexible, adjusting itself to any curves in the septum or outer wall of the nasal spaces, therefore causing no pressure necrosis and little or no distress.
2. It is of uniform size throughout, corresponding to the more or less uniform width of the nasal fossa and size of the anterior and posterior openings.
3. It may be cut any desired length. When used to prevent nasal hemorrhage it should be about 3 inches long, blocking both anterior and posterior nasal openings. When the tissues swell after the effects of the astringents used have disappeared, pressure is made against the splint, effectually retaining a clot within the nose.
4. Openings may be readily punched or cut with scissors in any part of the tampon to promote drainage or aeration. The remainder of the surface remains smooth, making removal painless.
5. When sufficiently long, 2½ or 3 inches, there is no tendency for the splint to escape from the nose. The pharyngeal constrictors push it forward sufficiently in the act of swallowing so that it does not press against the Eustachian tubes from which it is held medianward by the projecting turbinate. Its posterior end cannot tip upward sufficiently to permit the splint to slip from the nostril.
6. The anterior end of the splint can be cut at an angle to correspond to the opening of the nostril.
7. The splint may be used readily in the inferior part of the nasal cavity. When the upper part of the nose requires drainage or blocking, depending on whether there are openings or not in the sides of the splint, it may be cut a little shorter and the posterior end placed upward against or near the sphenoid or under the middle turbinate.
8. It is impossible, for lack of space, to place the metal or hard rubber splints far enough forward in the anterior part of the nasal space to support the nasal bones in case of fracture. These soft rubber splints can be placed well forward on either side or on both sides of the septum so as to support the nasal bones and septum. They can be prevented from slipping out of the nostril by adhesive strips from the cheeks across the nostrils.
9. These splints are useful to hold the septum in any fixed position after septal operations. If the septum tends to press to one side a splint on that side only will support it until fixed; in some cases a splint may be placed on each side of the septum.
10. With proper care, antiseptic or alkaline washes may be gently poured from an irrigator or fountain syringe through this splint cleaning it and the nasal fossa.
11. Very little distress is caused while introducing or removing the splint.
12. Air can readily pass through it, making the patient more comfortable.

The tampons or splints may be obtained in various widths and thicknesses and can be kept sterile, ready for use, in a weak dilution of liquor formaldehydi. Before they are introduced, a mildly antiseptic ointment, e. g., zinc oxid or 2 per cent. calomel ointment should be wiped over the outer surface of the splint. It may usually be removed within twenty-four or forty-eight hours, but if its use is required for a longer time its reinsertion is easy and painless. Ordinarily in inserting such a splint it should first be directed upward and backward until well within the nostril, then it should be gently pushed straight backward along the floor of the nose. If a long splint is pushed upward instead of directly backward it will come in contact with the middle turbinate or sphenoid causing distress instead of painlessly entering the posterior choana. The splint may be readily introduced by means of an alligator forceps passed nearly through it. The jaws of the forceps should be opened widely near the distal end of the splint to hold it from slipping farther on the forceps. If any part of the septum requires temporary support, which the first splint does not afford, a second short splint may be placed above the other or gauze packing may be inserted above any part of the splint. Clean air is the most healing balm to the inflamed or injured nasal mucous membrane and any solid substance in the nose acts more or less like a foreign body. Occasionally in nasal surgery, however, mechanical means to aerate, drain or hold certain parts in position are useful if not absolutely necessary.

165 East Market Street.

LYMPHANGIOMATA OF THE OMENTUM AND OMENTAL CYSTS *

STANLEY STILLMAN, M.D.
SAN FRANCISCO

The two cases that form the basis of this paper are of interest, not so much on account of their rarity as for the corroboratory evidence they furnish of the correctness of the theory of Jacobi, that true serous cysts of the omentum all have their origin in the lymph-vessels of the omentum. The reported cases of lymphangiomata of the omentum are limited to very few. Only two have been actually reported as such—one by Dewitzsky and Morosow in 1895, who reported a case of "pouch-shaped lymphangioma of the great omentum," the other by Wakefield of San Francisco in a paper read before the American Gynecological Society on May 7, 1907. In 1903, Schramm reported a case in a female infant 1 year old which he characterized as "cystic degeneration of the omentum." Besides my own case, the only other is reported by Reginald H. Fitz of Boston in the course of the Lane lectures in San Francisco in 1910. It was a case of enormously dilated lymphatics of the omentum, occurring in a woman who also had a fibroid of the uterus to which the omentum was attached. It had been noticed first three years previously and since, had slowly increased in size. The omentum was reduced to a web of connective tissue supporting the tremendously dilated lymphatics. The case was one of Dr. G. W. Brewster's of Boston, and the patient was operated on in the Massachusetts General Hospital in 1910.

My own patient was operated on September 1 of the same year; the case was almost identical with that of Dr. Brewster.

The patient was a woman of 42, married, with one child. She came to me on account of an abdominal tumor, which she had discovered herself four or five years previously, and which had steadily increased in size. Within the last few months, she had suffered considerably from pain and dragging, more referred to the epigastrium than to the pelvis. Examination disclosed a tumor the size of one's head attached to the uterus but quite freely movable. Diagnosis was made of pedunculated myofibroma of the uterus. During operation, it was found that the pedunculated fibroid was also attached to the lower border of the great omentum by a pedicle, as thick as one's thumb, and containing many large blood-vessels. When the omentum was pulled down, it was found to contain between its peritoneal surfaces numerous elongated, tortuous, exceedingly thin-walled cysts, which were in many cases from 1½ to 2 inches in diameter toward the free border of the omentum, and some tapered off almost to a point as they approached the lower border of the transverse colon. They were distributed throughout the omentum and varied in size and length. The gastrocolic omentum was similarly affected but to much less extent, and none of the tortuous dilatations were larger than a lead pencil. The total bulk of the affected omentum was very considerable, and while feeling certain at the time that we were dealing with a condition due to enormously dilated lymph-vessels, I was uncertain what course to take, but finally removed the entire omentum after ligating along the lower border of the colon. The blood-vessels, particularly the veins, were enlarged, many to the size of a lead-pencil. In the gastrocolic omentum, there was considerable fat, and the dilatations were much fewer, varied in diameter at different points of their course, and were unmistakably dilated and tortuous lymph-vessels.

Below the transverse colon, together with the large cysts, were others identical in appearance with those just described in the gastrocolic omentum, and it was plain that all, even the largest, were cysts formed by more or less enormously dilated lymph-vessels.

The cystic dilatations all presented the same general characteristics. The thin, transparent walls were lined with endothelium as well as covered by it. The fluid was clear, amber-colored in some and rose-colored in others, and the specimen presented a strikingly beautiful picture as it was withdrawn from the abdomen. Many of the elongated cysts closely approximated each other at their distal, expanded extremity and were only separated by an exceedingly thin membrane. The fluid was neutral in reaction and coagulated on boiling. Microscopically, it contained lymphocytes, multinuclear leukocytes and red blood-corpuscles in varying proportion in the different cysts. The intervening omentum contained little or no fat.

The cysts in both these cases all showed a characteristic lobulation or sacculation comparable to that of the distended colon, as can be seen in the photograph of Dr. Brewster's case. This is an important point, for it was noted in the case of Gairdner in 1851, the first reported case of cyst of the omentum, and proves his case to have been also really a cystic lymphangioma. The case was that of a woman who died unexpectedly and on autopsy was found to have a large fibroid uterus; in addition, a cyst was found, between the folds of the great omentum, measuring between 3 and 4 inches in length and from ½ inch to 1½ inches in diameter. "It was lobulated externally like that of the distended colon but in no part subdivided by complete septa, the fluid was a transparent colorless serum containing numerous flocculi." This case is unquestionably one of cystic dilatation of a single lymph-vessel. Whether in these two cases just reported, the adhesion to the fibroids bore any causal relation to the dilated lymph-vessels, I cannot believe, for the reason that such adhesions of the omentum are very common, but a resulting condition of the lymph-vessels, such as occurred in these cases, has never before been recorded. On the other hand, serous cysts of the omentum have formed adhesions at times to the parietes and other viscera, as might be expected, and very likely would form adhesions to a fibroid. That both these almost unique cases should have had so many other points in common, only goes to substantiate the doctrine of duality in rare affections.

The chief points of interest in these two cases are: first, the fact that the elongated cysts were unquestionably dilated lymph-vessels; second, that in many cases they were only separated by an exceedingly thin wall or septum; and third, that the blood-vessels between them and over them were in many cases greatly dilated.

Passing now to the consideration of cysts of the omentum, I am of the opinion after a critical review of the literature on the subject, that there have been twenty cases of serous cysts recorded, including one about to be recorded by me. To these, the cases of Brewster and myself may be added as multiple cystic lymphangiomata of the omentum, making a total of twenty-two cases. The case just referred to was seen some years ago in consultation with the late Dr. Brigham of San Francisco. The patient was a woman of 30, who had

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911

herself discovered a tumor in her abdomen five years previously. It had never troubled her but had slowly increased in size. On examination, a firm but elastic tumor about the size of the closed fist and movable in all directions was found a little to the left of the middle line of the abdomen just below the umbilicus. Apparently it was not attached to the uterus or ovary, both of which appeared to be normal. A diagnosis of either omental cyst or an ovarian cyst with a very long pedicle was made, on account of the absence of symptoms and the very free mobility. Operation was advised, but the patient declined to submit. A year later, however, the tumor was removed by Dr. Brigham, who found it was a unilocular cyst containing a pint of clear straw-colored fluid. Its walls were thin and covered with endothelium on both external and internal surfaces. It had no pedicle but was within the omentum, a considerable portion of which was removed with the tumor. The fluid was not examined.

Hasbrouck,[1] in 1907, collected reports of all the cases of cysts proper of the omentum up to that year, and placed the number at twenty, including his own. He did not, however, include a typical case of serous cyst reported by Schwarzenberger and operated on by Czerny in 1894, but he included several cases that, like his own, were malignant growths of the omentum with cystic degeneration and hemorrhages, and one that was due to perforation of a traumatic ulcer of the stomach, which had been protected by the omentum within the folds of which was a collection of sour-smelling fluid, containing particles resembling stomach contents, and which does not deserve to be called a cyst at all. Since his very complete abstract of cases in 1907, there have been cases of true cysts of the omentum reported by Wakefield in 1907, Seefisch in 1909, Rodman in 1909 and Gifford in 1910.

From this record, it is evident that true cysts of the omentum are of rare occurrence. Of reported cases of omental cysts in general, a few are hydatids, primary in the omentum (as is certainly possible) or cysts which, originating in the liver, have become attached to the omentum and in time become entirely separated from the liver, as is believed to be always the case by some observers. Several of the tumors are dermoid cysts, others are cysts decidedly of an ovarian character, either attached to the omentum or enveloped in it. These are believed to have had an ovarian origin in the first place, and subsequently gaining their blood-supply from the omentum, through adhesions, have gradually become detached from the ovary until they are at last entirely free from it and nourished by the omental vessels alone. In one such case reported by Ormsby,[2] the fimbriated extremity of the Fallopian tube was attached to a large cyst which was entirely free in the abdominal cavity except for an attachment to the omentum. It is not improbable that some of the solid tumors of the omentum originate in the same way. In my case, the pedicle connecting the fibroid with the uterus was considerably smaller than the one connecting it with the omentum, and was much less vascular. It seems very reasonable that in time it might have been entirely separated from the uterus. Chylous cysts of the omentum are not found in the omentum at all but in the mesentery, and not a single one is recorded in spite of the statements of some writers that they occur. Degeneration of lymph-glands, giving rise to semi-cystic growths in the mesentery, are recorded, and Rokitansky attributed the origin of some cysts of the omentum to this source, but I cannot find any record of such. Primary malignant disease of the omentum is not so infrequently met with, and may undergo cystic degeneration, and from hemorrhage give rise to enormous cystic tumors containing blood, as described by Hasbrouck. In some of the cases, it has been difficult to make out from the records whether they were of malignant origin or not, and these I have classed as doubtful; particularly is this the case where the cysts were multilocular and the contents greatly altered as a consequence of ancient hemorrhages into them. Secondary involvement of the omentum in malignant disease is quite common and of no particular interest whether cystic in character or not. Altogether there are recorded up to January of this year forty-three cases of cysts of all kinds, within or dependent from the omentum, which number the cases of Dr. Brewster and myself bring up to forty-six. Of the twenty-two which I believe to be true serous cysts, nine occurred at ages from 1 to 4 inclusive; six occurred from 5 to 11; the ages of the other patients were 17, 19, 22, 30 and 42, the remaining two were adults, age not stated; sixteen were females, six males.

If, however, one arranges these cases according to the ages at which the abdominal swelling was first noticed, we find that four and possibly five occurred between 1 and 2 years, six between 2 and 4 years, five between 4 and 10 years, three between 10 and 20 years, and only four above 20. In one of the last-mentioned cases the patient noticed the tumor six years before operation, at which time she was 21. In the remaining three cases the trouble was discovered by accident either at operation or autopsy

Abstracts of the histories of these cases are as follows:

Case 1 (Gairdner[3]).—*Woman, age not stated, died unexpectedly. At autopsy she was found to have a large fibroid uterus. In addition, a cyst was found between the folds of the great omentum measuring between 3 and 4 inches in length, and from a half an inch to 1½ inches diameter. It contained a transparent colorless serum, containing numerous flocculi.*

Case 2 (Gooding[4]).—*Girl, aged 18, noticed a lump about the size of a hen's egg low down in the right iliac fossa, which was painful, chiefly at menstruation. At time of operation, four years later, it was the size of a cocoanut. It was diagnosed as an ovarian cyst with a long pedicle. Operation disclosed a cyst in the gastrocolic formation firmly adherent to the parietal peritoneum and imbedded in the folds of the omentum. There was no pedicle.*

Case 3 (Spencer Wells[5]).—*Girl, aged 5, had had a large abdomen since infancy, growing steadily for past two years. On operation a single cyst of the omentum was found attached to the abdominal wall and cecum. It contained four pints of a clear, watery fluid. In the upper part of the omentum were a few small cyst-like collections of fluid resembling grapes. Some were removed, others simply pricked. A specimen was examined by Ransom, who found it to consist of three very thin-walled cysts, the largest holding a quart, the next half a pint, the smallest the size of an egg. There was no endothelium on the inner surface. He states that it was not hydatid; but he thought perhaps it was inflammatory.*

Case 4 (Erdheim[6]).—*Woman, aged 22, had a tumor, first discovered five years before, without known cause; according to the patient's account it reached its present growth in fourteen days. Operation disclosed a bluish, transparent cyst wall adherent over a wide area and covered with omentum. The tumor reached from the transverse colon to the bladder and had no conection with any of the pelvic organs.*

Case 5 (Marfan[7]).—The patient was a girl, aged 2½ years. Her mother had noticed that the abdomen had always been large and at the age of 15 months the enlargement began to increase and continued to do so steadily for the succeeding year. The general health was not affected until a few weeks before operation, when the child began to emaciate. An aspirating needle was inserted and about two liters of black hemorrhagic fluid evacuated. This gradually reaccumulated, and it was decided to operate. Operation revealed a multilocular cyst within the folds of great omentum. It had a pedicle and contained a large quantity of bloody fluid.

Case 6 (Hearn[8]).—The patient was a boy, aged 8. At birth, his physicians noted that the abdomen was markedly distended. This disappeared after a few weeks and was not again noticeable until he had become 6 years of age, when the abdomen began to distend. In the meantime, he enjoyed good health. Although the abdomen increased rapidly in size, the only difficulties he experienced were those due to distention and pressure. The abdomen was enormous, measuring 44 inches in circumference, and an omental cyst was suspected, owing to lack of symptoms of other troubles. Operation disclosed a cyst containing a dark yellowish-brown, turbid fluid and many other cysts. After evacuating a number, the mass was drawn out and found to be attached to the great omentum, between the folds of which it had developed. The fluid was alkaline in reaction and contained a large amount of albumin. Jacobi regarded this as a case of hydatid cyst and instanced it as a warning of the care and circumspection required in making an accurate diagnosis in cases of cysts of the omentum. From the history, however, I cannot see why this statement should have been made.

Case 7 (Braithwaite[9]).—Girl, aged 4, measured 22¾ inches at level of umbilicus; this had increased during two months. The tumor was found to be entirely within the folds of the great omentum and with the exception of adhesions to the intestine was easily removed. It contained 3½ pints of fluid.

Case 8 (Jacobi[10]).—The patient was a girl, aged 7. Four years previously the abdomen began to swell and the child lost weight. A diagnosis of tuberculous peritonitis was made, the abdomen tapped and two quarts of a clear, slightly bloody serum was drawn off. After two years the swelling returned and was tapped a second time. Subsequently it was operated on. Operation disclosed a large cyst, containing about 2 quarts of fluid, with a number of recesses communicating with the main cyst. It involved the greater part of the great omentum and narrowed into two pedicles as it approached the colon. The cyst was lined externally and internally with endothelium. The contents were gelatinous and finely granulated, and consisted of coagulated serum with multinuclear and eosinic forms of leukocytes, endothelial cells and a few red blood-cells. Staining by Weigert's method showed absence of fibrin.

Case 9 (Marsh and Monsarratt[11]).—The patient was a girl, aged 1 year 8 months, whose abdomen was noticed to be enlarged about four months previously, but there was no complaint of pain. It was tapped four times. Operation showed a thin-walled multilocular cyst springing from the gastrocolic omentum and entirely enveloped in it. It contained about 10 pints, and consisted of one large cyst and many independent smaller ones, and it had an attachment to the right iliac fossa. The external surface was covered with endothelium; internally it was lined by a coat of fine connective taissue containing numerous blood-vessels. The walls of the smaller cysts were better defined and afforded better support for the blood-vessels than in the large cyst, where the vessels were large and thin-walled.

Case 10 (Schramm[12]).—Female, aged 1 year. Swelling of the abdomen noticed four months before. Operation disclosed the fact that the entire omentum was made up of a conglomeration of cysts, varying in size from that of a nut to twice the size of the fist. About 3 or 4 cm. of the omentum, next the transverse colon, was quite normal. The cysts contained a clear rose-colored fluid.

Case 11 (Boyd[13]).—The patient was a boy, aged 11, whose health was excellent until a few months before operation, at which time his abdomen began to swell and the swelling steadily increased. He had constant pain in the lower abdomen, but never of a severe character, and he had become much emaciated. Operation disclosed a large, thin-walled cyst covered by and occupying the cavity of the great omentum and containing a large amount of greenish-brown fluid. The cyst was attached to the pancreas, but did not spring from it.

Case 12 (Schwarzenberger[14]).—Girl, aged 4¾ years, was operated on by Czerny. The cyst contained 3 liters of a clear serous fluid, and was multilocular. It was diagnosed as a lymph-cyst of the great omentum.

Case 13 (Young[15]).—Girl, aged 9½ years, had a swelling, noticed for more than a year previous. There was no pain. At operation, a thin-walled cyst was found containing many other cysts. It involved the anterior layers of the great omentum, part of which was normal and adherent to the stomach. It contained 32 pints, besides 5 or 6 that were lost on the floor, of a dark brown fluid, which was evidently broken-down blood and serum. The fluid in the cyst was not examined.

Case 14 (Matthews[16]).—Boy, aged 8, nine months previously he had complained of pain in the left side, following which there was a gradual distention of the abdomen. This continued till the abdomen measured 27 inches. On operation a cyst was found containing 6 pints of a dark brown fluid. It was attached to the transverse colon by a thick pedicle, made up of omentum.

Case 15 (Fort[17]).—Girl, aged 2½, had an abdominal enlargement, noticed eighteen months previously. At the time of operation the abdomen measured 28 inches. There were no symptoms other than dyspnea. Operation disclosed a cyst between the layers of the great omentum containing an enormous collection of fluid. There was an absence of distinct capsule other than the peritoneal covering of the omentum, the fluid being between the folds of the omentum.

Case 16 (Wakefield[18]).—Boy, aged 4, had an enlargement of the abdomen; noticed at least two years before. At the time of the operation, the abdomen was enormously distended. Operation disclosed a tumor larger than a man's head, consisting of a number of various sized thin- and clear-walled cyst chambers, the bulk of the mass being made up of a single cyst. The fluid contained in the cyst was clear, straw-colored and neutral in reaction. It coagulated on heating with a drop of acetic acid.

Case 17 (Rodman[19]).—Patient was a girl, aged 17. On operation, a cyst which, together with its contents, weighed 60 pounds was found beneath the parietal peritoneum, covered by another layer of peritoneum. It had no pedicle, was unilocular and contained a clear fluid. It shelled out like a walnut, only one small vessel being tied.

Case 18 (Seefisch[20]).—Patient was a boy, aged 4, whose mother had noticed a swelling in the abdomen a short time before. On operation, an enormous cyst was found dependent from the hepatic flexure of the colon by a pedicle the thickness of a lead-pencil. The contents measured from 2½ to 3 liters. The wall of the cyst was very thin and consisted only of the web of the great omentum.

Case 19 (Gifford[21]).—Boy, aged 6, had a swelling, first noticed six months previously, when the patient complained of pain in umbilical and hypogastric regions. On operation, a cyst the size of a cocoanut was found in the substance of the omentum and was adherent to the anterior abdominal wall. The omentum was ligated and divided and the cyst easily removed. It was multilocular and contained a clear straw-colored fluid. The interior of the cyst wall was lined with a smooth membrane.

There are three cases that I regard as doubtful. One is a case reported by Simon[22] in 1858. The patient was a man, 44 years of age, who had a large tumor of the abdomen, which had been present to his knowledge for twelve years. It had never pained him. He died five days after admission to the hospital, and at autopsy a thick-walled cyst was found in the omentum, full of coagulated blood. It might have been an endothelioma or some other malignant growth with cystic degeneration. Another case was reported by Cazin,[23] in 1893. The patient, a man aged 48, had a tumor which had developed without known cause and had gradually enlarged. It was diagnosed as a cyst of the pancreas, but operation showed it to be a cyst of the great omentum adherent to the large intestine. The third case was reported by Edebohls,[24] in 1893. The patient, a woman aged 37, had noticed the enlargement eight [illegible] On operation, a cyst containing a [illegible], was found attached to the lower border of the omentum by a pedicle 10 cm. wide and 2 cm. thick. A large circular area opposite the pedicle was gangrenous. The case was probably originally a cyst of the ovary with a pedicle, which had become attached to the omentum and subsequently separated from the ovary.

There are several cases to the histories of which I have been unable to gain access. Dewitsky and Morosow[25] in 1905 reported a case of "pouch-shaped lymphangioma of the omentum." Giannettasio[26] in 1907 reported a case of blood-cyst of the omentum. Karas[27] reported a case of multilocular cyst of the omentum in 1907. Holleman[28] reported an omental cyst in 1908. Costa[29] reported a case of cyst of the great omentum in 1908. Villar[30] reported a case of cyst of the lesser cavity of the omentum in 1908. These, however, I do not think would affect the general conclusions arrived at in this paper.

As to the etiology of the conditions of the omentum with which this paper is principally concerned, Jacobi stated in his paper on "Cysts of the Omentum" read before the Association of American Physicians in 1901, that he believed most, if not all, of them had their origin in the lymph-vessels of the omentum. Hasbrouck believes most of them to be endotheliomata and disbelieves that many have a congenital origin. Wakefield believes most of them t[illegible] Many express their belief in a [illegible] own particular cases.

It is exceedingly significant that the swelling of the abdomen was first observed at some period between 1 and 10 years of age in fifteen of the twenty-one patients operated on, and in ten of these, or nearly one-half of all the cases, the swelling was noticed between 1 and 4 years of age. This, I think, must speak for a congenital origin.

We find congenital cystic lymphangiomata in other parts of the body, notably in the tongue and root of the neck, and I think the condition in question comparable to the latter—the so-called "cystic hygroma of the neck" which may attain a very considerable size.

The two cases that form the basis of this paper were in adults and were unquestionably cystic lymphangiomata—so also was Gairdner's case.

In Hearn's case the abdomen was noted to be enlarged by the patient's physician at birth, but as the child grew the swelling disappeared, to be noted again at 6 years, from which time it increased till operation two years later. Spencer Wells' patient had three large cysts and many independent smaller ones, some of which were pricked and others removed. This case was in a child of 5, whose abdomen had slowly increased in size since infancy.

In Jacobi's case, the swelling of the abdomen was noticed when the child was 3 years of age. A large cyst was found, which had many recesses communicating with it through large openings.

In Marsh and Monsarratt's case, in an infant in whom swelling of the abdomen was noticed at 16 months of age, a large cyst was found and many independent smaller ones.

Schramm's case was in an infant of 1 year. Operation disclosed the fact that the entire omentum was made up of a conglomeration of cysts varying in size from that of a nut to twice the size of the fist. The 3 or 4 cm. of the omentum next the transverse colon was quite normal. This description might very well be applied to either Dr. Brewster's case or mine.

Wakefield's case had a tumor consisting of a number of various-sized thin- and clear-walled cyst chambers, the bulk of the mass being made up of a single cyst. The swelling of the abdomen was noticed first at 10 years of age and the child was operated on two years later.

In most of these cases the cyst contents were similar to those found in the three cases in adults that were discovered accidentally.

It would seem that the variations in the individual cases can be readily explained as follows:

In some there was but a single lymphangioma, as in Gairdner's case; in others, many of them. As these increased in size, the delicate septum between some of them broke down forming a large cyst around or within which were others in which the septum was intact; thus a multilocular cyst would be formed of various-sized cysts around a large one.

Jacobi's case would seem to bear out this idea, for in his case portions of the septa were left between the cysts and the cyst narrowed into *two* pedicles as it approached the colon. In some cases the cyst was lined with endothelium, in others not. The latter would be very likely the case if the cyst or cysts ruptured between the layers of the peritoneum constituting the omentum, and increased in size by simply separating these layers.

It was noted in many of the cases, particularly of the larger cysts, that the blood-vessels were large and thin-walled and poorly supported by connective tissue, and it is reasonable to suppose that these dilated and thin-walled vessels should also occasionally rupture. This admixture of blood at various times and in various amounts, with the original cyst contents, would explain the difference in the character of the fluid found in different cysts and also perhaps the rapidity of growth observed in some of the cases.

These various changes might take place slowly or rapidly—in most cases rapidly, as shown by the fact that operation was called for in so many of the cases within the first ten years of life. In others no inconvenience was occasioned till later in life and in some the

condition was only discovered by accident, either at operation or at autopsy.

So far as diagnosis is concerned, it has been observed by all writers that this is practically impossible before operation. Most of the cases have been mistaken for tuberculous peritonitis with ascites, or for an ovarian cyst with a long pedicle. In cases of moderate-sized cysts originating below the colon, in which adhesions have not taken place, the free mobility and absence of symptoms referable to any other organ might give rise to a suspicion of the nature of the cyst. In those that fill almost the entire abdomen or are adherent, or originate in the gastrocolic omentum, the diagnosis is practically impossible before operation. All of these patients recovered from operation, although some of the cysts were enormous. In Rodman's case, in a girl of 17, the cyst and contents weighed 60 pounds, and in Young's case, in a girl of 9½, the contents measured 32 pints, besides 5 or 6 that were lost on the floor.

Dr. Fitz stated, in regard to my case of multiple cystic lymphangiomata, that, had I not removed the omentum, there was every reason to believe that in time a large cyst might, could or would have developed. I think there is every reason to believe that in all these cases of true serous cysts, the cysts could, would and did develop from congenital cystic lymphangiomata of the omentum.

2101 Webster Street.

ENDEMIC MEDITERRANEAN FEVER (MALTA FEVER) IN SOUTHWEST TEXAS

THOMAS L. FERENBAUGH, A.B., M.D.
First Lieutenant Medical Corps, U. S. Army; Surgeon, Camp U. S. Troops, Del Rio, Texas

During recent years there have been a few cases of continued fever of long duration, frequent relapses and a low mortality, in the Pecos River country. Four such cases recently occurred in the practice of Dr. R. M. Scott, of Del Rio. The four patients, all young men from 11 to 20 years of age, had worked at a goat camp where they had lived for three months, quartered in a house surrounded by the dusty bedding ground of the goats and were using goat's milk from the herd, some of which were ill of "goat fever." The fact seemed significant and it was suggested by me to Dr. Scott that the fever was possibly Mediterranean fever. After agglutination tests had been made with the *Micrococcus melitensis* on the four cases with positive results, Dr. S. L. Boren mentioned that he too had a patient, a goat ranchman, ill of continued fever with symptoms not unlike those manifested by the four boys. An agglutination test with the *Micrococcus melitensis* was positive in this case also.

The following is a brief history of each case and the result of the agglutination tests. Malaria was excluded in each case by blood-examination. Quinin given in large doses over a period of two weeks had no marked effect on the temperature in any of the five patients.

Case 1.—C. E., aged 12, was a goat herder, whose family and personal history were unimportant, except that the patient had chills and fever three years ago in east Texas. The present illness began May 10, 1911, with slight evening temperature, chilly sensations, headache, especially pains at the back of his neck and in right ear. The patient had general aches and pains, especially in both knees, wrists and arms. He was brought to Dr. Scott at Del Rio for treatment, May 19.

Examination.—The patient was found to have an enlarged spleen, tympanites, profuse sweating, nose bleed and obstinate constipation. Both wrists were painful on pressure. The temperature ranged from 102.5 to 103 F. From June 20 to 23 the patient was free from fever, then it returned to 103 without obvious cause. He had diarrhea for two days followed by obstinate constipation, pains all over the body, tympanites, and profuse sweating as before. July 1, he appeared very emaciated, anemic and severely ill. His temperature ranged from 99 to 102.5 F. daily.

Agglutination tests—macroscopic method: *Bacillus typhosus*, 1-50, negative. *Micrococcus melitensis*, 1-50, positive in 15 minutes. Normal control—negative.

A report from the Maneuver Division Laboratory, San Antonio, Texas, by Lieut. George B. Foster, M.C., and Lieut. Taylor E. Darby, M.C., stated that serum from Case 1 gave positive agglutinations with the *Micrococcus melitensis* in dilutions of 1-80, 1-160 and 1-320 in 10 to 45 minutes by both the microscopic and macroscopic methods. Typhoid control, 1-40 negative; normal controls, 1-20 negative.

Case 2.—L. E., aged 11, was a goat herder, whose family and personal history were unimportant, except that the patient had chills and fever in 1908 in east Texas. The patient became ill May 16 when he began having an evening temperature, headache, ear-ache and pains in the back of his neck. At times he felt chilly, but he had no definite chill. He went to bed May 20, and May 30 he was brought to Del Rio. When the patient arrived, he had a slight temperature, but it soon returned to normal and remained so for five days when it returned to 101 F. followed by diarrhea and two days later by obstinate constipation. The temperature remained at 99-100.4 F. until June 20 when it again became normal for three days. The fever returned and remained at 99-100.2 F. until July 1, when it reached normal. During the last relapse the patient suffered severely with his hip, which was so painful it could not be moved. At present he is somewhat emaciated and very anemic.

Agglutination tests—macroscopic method. *Bacillus typhosus*, 1-50, negative. *Micrococcus melitensis*, 1-100, positive in 20 minutes. Normal control, negative.

Case 3.—K. E., aged 12, was a goat herder, whose family and personal history were unimportant, except that the patient had chills and fever in east Texas in 1908. The patient became ill May 20 with fever at night, headache, pain in the back of the neck and ear-ache. He ached all over, being especially sore in his arms. The bowels were constipated. When brought to Del Rio for treatment, he had some tympanites, enlarged spleen, profuse sweating and nose bleed. His temperature was 100-101 F. June 18, the temperature returned to normal, but June 20 it went up to 104 F. followed by diarrhea, headache, and profuse sweating. The fever then remained at 100-101 F. and July 1 it had again reached nearly normal. He is also anemic and somewhat emaciated.

Agglutination tests—macroscopic method. *Bacillus typhosus*, 1-50, negative. *Micrococcus melitensis*, 1-50 positive in one hour. Normal control, negative.

Case 4.—R. E., aged 20, was a goat herder, whose family and past history were unimportant, except that the patient had pneumonia in 1907. He became ill May 20 with slight sore throat, headache, bone-ache, "dumb chills" and fever, first in the morning, but later it became high at night. The patient had a cough and spit up stringy sputum. The bowels were normal and the appetite good. After the illness began, the patient left home and traveled through Mexico and New Mexico where he consulted several physicians who advised him to go to a hospital. After spending a few days in a hospital in El Paso, he came to Del Rio, June 10. When seen by Dr. Scott, he had tympanites and enlarged spleen. His temperature was 99-99.5 F., but became normal June 15. June 18, he returned home and the fever again appeared with intense pain in his shoulder and knee and later in the elbow. When seen by me, the patient would cry out if any attempt was made to move his elbow or shoulder. He is very anemic and looks decidedly ill. His temperature was 102 F. at the time of the examination. The patient eats heartily and sits around the house taking an interest in everything.

Agglutination tests—macroscopic method. *Bacillus typhosus*, 1-50, negative. *Micrococcus melitensis*, 1-50, positive in one hour. Normal control, negative.

CASE 5.—L. H., aged 35, is a goat ranchman whose family and personal history are unimportant. He became ill May 15, 1911, with headache, especially with pain at the back of his neck and general pains all over his body, which he called "rheumatism." The patient had some cough, a slight fever with a chilly feeling and some sweating. He came to Del Rio May 30, riding forty miles for treatment, in a carriage. When he was seen by Dr. Boren, his temperature was 103.5 F. He had slight tympanites, enlarged spleen and had to have medicine to move his bowels. He had one severe nose bleed. In four days the patient was clear of fever and returned home June 7 feeling well, except for weakness. June 11, the fever returned with pains all over his body, the ankles became swollen and painful and he had severe pains in both shoulders and in the back of the neck. The right testicle became swollen to three times its normal size. He then returned to Del Rio June 23 for treatment. Although always rather light in weight, he lost twenty-one pounds and is extremely emaciated. His anemia presented the blood-picture of a severe secondary type. No leukocytosis was present. The spleen is still enlarged and the bowels constipated. His appetite is good. The temperature now ranges from 99.5-101 F. He states that he has never drunk goats' milk, but that he has worked with his goats, feeding and herding them.

Agglutination tests—macroscopic method. *Bacillus typhosus*, 1-50, negative. *Micrococcus melitensis*, 1-50, positive in 15 minutes. Normal control, 1-20 and 1-50, negative.

A report from Major F. F. Russell, M.C., and Captain Charles F. Craig, M.C., of the Bacteriological Laboratory, Army Medical School, on the blood from Case 5 states that agglutinations were secured in dilutions up to 1-640; normal controls 1-20, negative.

It is possible that the goats of the Pecos River country, and doubtless along other sections of the border, are infected with the *Micrococcus melitensis*. The drinking of goats' milk in the Pecos River country is not common except among Mexicans and those located at isolated goat camps. Along some sections of the border I am told as much goats' milk is drunk as cows' milk, this being especially true for the Mexican population.

This endemic occurrence of Malta fever in Texas is now being further investigated by Lieut. Gentry and myself.

THE SURGICAL TREATMENT OF MEGACOLON [*]

WALLACE I. TERRY, M.D.
SAN FRANCISCO

The term "megacolon" is used to include the different forms of chronic dilatation of the colon, whether of congenital or acquired origin. Hirschsprung's disease includes only the congenital, and so far as we know, the idiopathic dilatations of the colon. As it has been impossible in the majority of the reported cases to determine, either at operation or autopsy, whether they were really congenital or acquired, it would seem best to describe them as cases of megacolon. The term "pseudomegacolon" is a misnomer, for if there is a megacolon at all, it can scarcely be called "pseudo."

The etiology of this condition is obscure. There are undoubted cases which show that it is often congenital, such as the cases of Konjetzny[1] in a fetus of seven months and in a child of three days, while the occurrence of cases in individuals from 50 to 88 years of age, would tend to put some of them in the category of acquired megacolon. In a fair proportion of the reported cases there has been obstruction of the bowel by tumors, by strictures, by kinks, by valve formations or by spastic contraction of the rectum or anus, but in the great majority of cases no such obstruction can be found. There are a number of theories to account for the latter group, among which are to be mentioned the following: Abnormal length of the mesosigmoid; abnormal length of the sigmoid; chronic colitis; neuropathic changes in the sympathetic system; and defective development of the muscular coats in some part of the colon. Indeed, it would seem, as Finney[2] and Schmidt[3] have stated, that no one theory yet advanced is a sufficient explanation of the etiology of all the cases.

Pathologically we find a number of interesting features in megacolon: great distention of the abdomen; thinning of the abdominal walls; increase in the length of the colon; dilatation of the colon even up to 10 inches in diameter; hypertrophy of the wall of the colon (in one case, reported by Finney, it was 3.55 cm. or 1⅜ inches, and others have reported a thickness of 2 to 3 cm.); and changes in the mesocolon, generally a hypertrophy. The sigmoid is more apt to be dilated than any other portion of the colon, and in a series of 104 cases analyzed by Puls, it was found that the sigmoid alone was the seat of the disease in 35 per cent., the entire colon was dilated in 27 per cent., and the sigmoid, either alone or with other segments, was involved in 84 per cent. of the cases. Occasionally coproliths of large size are present, as in one of the cases I am about to report.

In a small proportion of the cases a practical cure can be obtained by medical treatment, regulation of the diet, massage of the abdomen, irrigation of the colon and the proper use of laxatives and cathartics. The success of medical treatment will depend in large measure on the tonicity of the colon and the contraction of its lumen to normal or slightly above normal size. When, however, there is a definite obstruction which causes the dilatation, or medical treatment fails after a reasonable time, the condition becomes surgical and operation should not be delayed.

A few cases have been reported in which no further surgery than a dilatation of the rectum or a division of rectal valves was necessary to effect a cure; in others the removal of tumors pressing on the rectum has given good results.

The great majority of cases, however, require some direct interference with the dilated colon, and along these lines a number of different procedures have been advocated. The establishment of a fecal fistula, or an artificial anus, is advisable as a temporary expedient for acute obstruction or as a safety-valve in some of the more elaborate anastomoses or resections. Finney emphasizes the value of making a colostomy in healthy bowel above the dilated segment. As a curative measure it is scarcely justifiable, for few patients would tolerate it as a permanent proposition, unless all other means had failed to cure.

Colotomy with the removal of fecal tumors has been resorted to a number of times, when the masses have been too hard to break up without endangering the bowel. It is interesting to note that the presence of coproliths has often led to errors of diagnosis. In a case reported by Kraske, a segment of the colon containing a coprolith was resected in the belief that it was a true tumor. Puls[4] reports a case in which Delkeskamp removed a coprolith and immediately sutured the opening in the colon. Twenty months later another coprolith had formed and after removing it by a colotomy, he made an ileosigmoidostomy resulting in a cure.

---

Colopexy, either a high or a low fixation of the bowel, has proved of value in a few cases, but it would ordinarily be contra-indicated because of the bad effects of fixation of a mobile portion of the colon to the abdominal wall.

Coloplasty, based on the principle of pyloroplasty, has been done a few times without notable success.

Longitudinal plication has been done ten times with six successes and four failures. Bastianelli is credited with having first performed this operation and, so far as I am able to ascertain, it was next done in one of the cases I am about to report. I am inclined to believe that, like colopexy and coloplasty, it will not play any important part in the operative treatment of megacolon.

Exclusion of the bowel by various anastomoses is an important procedure and has been successfully used in many of the reported cases. The anastomoses to be made depend on the particular case, but as a rule an ileosigmoidostomy or a colocolostomy are the operations of choice. In a few cases, the anastomosis of ileum and sigmoid has led to severe diarrheal troubles, but the procedure is generally well tolerated. It has also been [illegible] that the short-circuiting operations did not always [illegible] cking of the excluded bowel with fecal matter. [illegible] owever, an entero-anastomosis fail to give a [illegible] sult, it does not usually interfere with a resec[illegible]on of the remaining dilated colon.

Resection of the giant colon would seem to be the ideal operation. It is a more formidable procedure than any of the above-mentioned and should not be done as the primary operation in a fair proportion of the patients already much weakened by the effects of a megacolon. I believe, however, that more primary resections will be done in the future, now that we have learned better how to prevent and combat shock. Earlier diagnosis of the disease and further improvement in the technic of intestinal resection, will also be important factors in the successful treatment of megacolon.

The two cases which I desire to report seem to have been true cases of Hirschsprung's disease, generally designated in English literature as "congenital idiopathic dilatation of the colon." The first case is an unreported one of Dr. T. W. Huntington, and it is by his courtesy that I am putting it on record. The original case history was lost in the San Francisco fire of 1906.

Case 1.—Mrs. G., aged 28 years, with unimportant family history, had always been rather delicate and had suffered for many years from chronic constipation, from which she obtained relief by the daily use of enemas or cathartics. She came under the care of Dr. Huntington in the early part of 1901, complaining of a mass in the upper abdomen which had been noticed for two years and was gradually increasing in size. The mass was about 6 inches in diameter, was firm and very freely movable from side to side. The patient was seen by several other physicians, but the correct diagnosis of fecal tumor in a megacolon was not made until the operation. At the operation, in which I assisted Dr. Huntington, an enormous dilatation with thickening and lengthening of the entire colon was found. The hard fecal tumor was in the transverse colon, and by manipulation was broken up and later washed out through the rectum, there being no stricture of any kind in the bowel. Having in mind plication of the stomach for dil [illegible] of th [illegible] on, I suggested a longitudinal plication of the colon, which was carried out by means of several rows of sutures. The patient recovered nicely from the operation and is now, ten years after the operation, perfectly well, although she has never obtained a weight above 115 pounds. The bowels are regular without artificial aid.

Case 2.—W. S., aged 20, male, single, good family history, had been feeble-minded since early childhood. Patient never had a natural bowel movement since birth, cathartics or enemas being always necessary, and the services of a physician being frequently required to secure relief. The abdomen had always been large and protruding. April 1, 1909, I was called in consultation by Dr. J. T. Gardner, who stated that the boy had not had a bowel movement for three weeks past and that despite the washing out of a large mass of impacted feces and repeated enemas, the marked distention of the abdomen persisted. Tympany was present all over the abdomen except in the right flank. The abdominal wall was thin, peristalsis visible and violent, and loud borborygmi frequently heard. On auscultation a metallic tinkle was heard over the lower abdomen and in the splenic region. No tumor mass was palpable. I made the diagnosis of megacolon and advised immediate operation on acount of the marked obstruction. At the operation, the same day, a median incision was made and there was found a megacolon involving principally the descending colon and sigmoid. The cecum was considerably larger than normal, while the sigmoid was 19 cm. (7½ inches) in diameter. The walls of the dilated bowel were much thicker than normal. Much fecal matter and gas was emptied out by means of rectal tubes, and a longitudinal plication was then performed by means of several rows of linen sutures. The abdominal wall was very thin, there being practically no panniculus adiposis, and the muscle fibers were widely separated. No satisfactory bowel movement could be obtained after this operation, and as the distention reappeared, the abdominal wound was torn asunder, permitting a loop of small intestine to protrude. An enterostomy was, therefore, made a week after the first operation, utilizing the protruding small intestine for that purpose. The patient now began to improve and four months later (Aug. 17, 1909) an attempt was made to close the artificial anus, in the belief that the colon had contracted, but the sutures failed to hold. On Sept. 3, 1909, an incision was made at the outer border of the right rectus, the ileum cut off and laterally implanted in the sigmoid. The artificial anus was found to be four feet from the termination of the ileum and was closed by a resection and a side-to-side anastomosis. It was found at this operation that the sigmoid was again dilated to its original size, but that the plication of the descending colon had been successful in reducing its caliber. The patient survived the last operation only six days and the cause of death could not be determined, an autopsy not being permitted.

In this second case, I feel that it was an error of judgment to perform a longitudinal plication at the first operation and that a primary colostomy in the cecum or colon, followed later by a resection of the dilated portion of the colon, would have been a better procedure.

I have been able to collect reports of 110 cases of megacolon treated surgically, with eighty-two recoveries and twenty-eight deaths: i. e., 74 per cent. and 26 per cent., respectively. Excluding fifteen cases in which nothing more than an exploratory laparotomy was done, we have ninety-five cases with seventy recoveries (73 per cent.) and twenty-five deaths (27 per cent.). The statistics of Loewenstein, made four years ago, showed a mortality of 48 per cent. out of forty-four cases subjected to operation. It would appear as though the death-rate had either decreased rapidly within the past few years, or else that proportionately more of the successful cases had been reported. The latest statistics regarding the medical treatment which I have been able to procure are those of Loewenstein in 1907, which show fifty-nine patients treated, with 34 per cent. recoveries and 66 per cent. deaths.

ABSTRACT OF DISCUSSION

Dr. J. F. Percy, Galesburg, Ill.: I lost one of these patients just a few weks ago, and because the members of this Section are liable to have cases brought under their observation at any time, I think it is well to mention them in connection with the paper.

The patient was a farmer, aged 77; he had a history of what he and his family called dyspepsia, extending over the period really of his whole life; and the attacks of obstruction of the bowels, which were peculiar to this case, were always ushered in after a spell of intoxication. He was a periodical drinker. But he had always been relieved by the use of cathartics. When I saw him a few weeks ago he had been in bed two weeks, he had had 6 drops of croton oil, an unknown quantity of calomel, and a member of the family said he had been given 15 cents' worth of magnesium sulphate at one dose. Most of you can estimate the size of the dose. He was delirious, and the abdomen was moderately and equally distended. Pressure over any part of the abdomen elicited pain, but there was nothing that could be localized. I made an indefinite, tentative diagnosis of twist of the colon. I really did not know what I meant by that, but that was my diagnosis, and I gave a bad prognosis and advised that he be sent to the hospital, which was done.

On opening the abdomen it was found that it was entirely filled with the sigmoid and the descending colon. I made an inguinal colostomy rapidly and put the patient to bed. He died in about thirty-six hours. A feature of the case was the enormous amount of fecal matter, equaling a large water-pail full.

In the diagnosis before operation (and it was peculiarly true in this case) the important point is the history of years of suffering from intestinal pain, which in this instance had been relieved by enormous quantities of cathartics. The history along this line was really quite remarkable. But there came a time when cathartics did not relieve him.

Mr. Harold J. Stiles, Edinburgh, Scotland: I have met with this condition in the children's hospital in Edinburgh and also in my adult service. It is easy to diagnose in children, not only from the physical signs, but from the history which the mother will always give. The child is generally brought to the physician when it is a few years old, because of the obstinate constipation and the relatively enormous enlargement of the abdomen. The mother will tell you that the constipation has been obstinate ever since the child was born, and that it gets gradually worse and worse, and that the abdomen gets bigger and bigger. During this time there is a high degree of fecal obstruction. The bowels sometimes do not move for from two to three weeks, and then a copious and continuous diarrhea occurs with frequent intervals of colicky pains, as the previous speaker has said.

The best thing to do is to open the abdomen and anchor very securely this enormous colon to the abdominal wall, and then open the bowel at once, or a day or two afterward, as the urgency of the case may require. My experience is that some of these patients get along perfectly well with the simple colostomy. In the case of a boy aged 8, colostomy was done five or six years ago; all the distention is gone and the boy is perfectly well. There is only a little leakage when the child's bowels are loose, and the only inconvenience is the passage of wind through the opening, which relieves the tension and prevents the obstruction.

I have tried in a child of 3 the effect of doing a sigmoidectomy. Before the operation is done, care must be taken that the enormous sigmoid flexure and colon are thoroughly well emptied. If they cannot be emptied, preliminary sigmoidostomy should be made before the radical operation. In a little child the small intestine is no bigger than the finger, and the colon may be as large as the lower part of the thigh, and there is danger from the pressure of the large sac against the relatively thin small intestine. In the first case I was very anxious about the patient. For three or four days the child vomited continuously, but at last it got relief and recovered.

In elderly people, with a history of chronic constipation and intermittent obstruction for many years, here, again, the safest thing, I think, is preliminary colostomy. Then at the secondary operation I have done a resection of the sigmoid and as much of the large intestine as was necessary. In one case after doing this the symptoms recurred. Why? Because the distention extends right down to the rectum, and the whole of the sac cannot be resected. Several months after an end-to-end anastomosis it will be found that the same portion of the intestine is again greatly distended at the seat of operation. In that particular case, that of an elderly man, what I had to do was to make a small opening, and ultimately the patient was permanently relieved. There was very little leakage, but enough escape of gas to prevent the patient from getting obstruction.

Dr. Wallace I. Terry, San Francisco: One point suggested by Professor Stiles' discussion is the use of the vermiform appendix as a permanent opening for the escape of gas. The appendicostomy should only be supplementary to some further operation on the megacolon.

THE USE OF SODIUM HYDROXID FOR STERILIZING INSTRUMENTS

ISAAC M. HELLER, M.D.
Adjunct Ophthalmologist and Otologist, Lebanon Hospital
NEW YORK

The profession is so busy along scientific lines that some practical points are often overlooked though their value may be unquestioned. Having for two years used sodium hydroxid ($NaOH$) in solution for sterilizing boilable instruments, with great satisfaction, I was somewhat surprised to find no mention thereof in books on operative surgery and gynecology. In looking over fifteen of the representative works, I find that in the majority it is advised to boil the instruments in "soda," or "washing soda," or "sodium carbonate" (Na_2CO_3), in strengths from .5 per cent. to 1.5 per cent. In one book sodium bicarbonate ($HNaCO_3$) is recommended. Instruments, especially if plated, boiled in such a solution come out covered with a white scum, are slippery and unless quickly dried, are liable to turn back, often defying diligent scouring. This is particularly true if there happen to be some blood thereon.

Sodium hydroxid, or hydrate, or caustic soda ($NoOH$), has none of these faults when used in a 0.25 per cent. solution. It comes in pearly sticks the caliber of a pencil and 4 to 6 inches long. A piece ¾-inch long (about 38 grains) to one quart of water gives the approximate strength. Inadvertently, I have left instruments standing in such a solution over night and have been agreeably surprised to find them neither black nor rusted in the morning. Fresh blood-stains disappear as if by magic when rinsed therein, and old dried spots are easily removed with a little rubbing. I have succeeded even in removing dried blood from rubber aprons with some of the solution left after sterilizing instruments, which had resisted previous scouring. It may be used hot and it is well known that plain hot water will clot and harden blood, making its removal the more difficult. It is my custom to have a basin of the solution handy while operating and by rinsing the instruments therein for a few seconds, they are kept always clean. While not able to prove this, I feel convinced that the instruments retain their plate longer and look brighter than before I used the hydrate.

Compared with sodium carbonate, the only disadvantage lies in the cost. The wholesale price of the hydrate is 35 to 40 cents per pound for the pure and about half that for the commercial product. The latter I have never used, so cannot say if it is equally serviceable. The chemically pure carbonate costs 25 cents, while the common grade, full of impurities and extraneous substances, can be obtained in the grocery stores for 3 to 5 cents per pound. The amount used at any one time, however, is so small that the expense can be of little moment to any one, except, perhaps, in large hospitals where sterilization goes on more or less constantly. I am quite sure that the surgeon giving the hydroxid a fair trial will not care to return to the use of the carbonate or bicarbonate. Owing to its high degree of deliquescence, sodium hydroxid must be kept in tightly stoppered glass bottles, preferably wide-mouthed.

I claim no originality for this discovery, for Mr. H. Leiter, the instrument manufacturer of Vienna, brought it to my attention.

Another little "stunt" worthy of mention is to rub lightly those metal instruments to be left in the case for some time with a stick of cocoa butter so that a thin film is deposited. This has the advantage over petrolatum, so generally recommended, that it is not disagreeably greasy to the touch and shelves, does not attract and hold dust, while it is equally effective in preventing rust.

450 Tremont Avenue East.

PERFORATION OF PREGNANT UTERUS IN AN UNSUCCESSFUL ATTEMPT TO PRODUCE ABORTION

K. F. SNYDER, M.D.
FREEPORT, ILL.

The question of the amount of trauma to which the pregnant uterus may be subjected without aborting is one which frequently comes up before us in many phases, particularly as regards the matter of operating during the term of pregnancy. I report the following case as being unique, so far as I can find, in the amount of damage done to the uterus without producing a miscarriage.

July 11, 1910, I was called by Dr. A. F. Kober, of McConnell, Ill., to see with him a patient who was apparently aborting. The patient was a woman of 35; was flowing to moderate extent; temperature, 101; pulse, about 120; and a very rigid abdomen over the uterus. She had been sick about two days before calling Dr. Kober, and delayed assistance as long as she could.

She gave a history of having attempted to bring on a miscarriage by the introduction of a twig of slippery elm. She stated that she had frequently used this means of inducing her menses when over time and had never had any previous trouble with it.

Dr. P. J. Burrell, of Winslow, Ill., was called in, and under anesthesia the patient was more thoroughly examined by introducing a sound and it was then discovered that the posterior wall of the uterus had been perforated through the cervix. On this finding, the patient was immediately hurried to the hospital and the abdomen opened. We found an infected tract extending from the perforation in the uterus along the upper portion of the sigmoid, and lying among the walls of the small intestine a number of small abscesses with a localized peritonitis about. The omentum lay partially in the perforation in the posterior wall of the uterus, whose edges were necrotic, and was about 4 cm. in diameter. The abscesses were evacuated and carefully drained, the omentum was amputated and removed, and also drainage established through the perforation and the cervix to the vagina. Nothing was done with the uterus, as regards emptying, more because of the condition of the patient than because it was considered the best policy to pursue, though it did not occur to us at the time that the ovum might still be present.

After a moderately severe convalescence the woman recovered and came to good health, believing of course, that the attempt at abortion had been successful.

The patient was dismissed from my mind and service, and it was with great surprise that on Jan. 1, 1911, she came in and I found her pregnant about seven months, as I diagnosed it at that time. March 28, Dr. Kober delivered this woman of an 8-pound child after a labor of moderate severity, with no untoward incidence, showing that the woman was probably about six weeks pregnant at the time she attempted to bring on her miscarriage.

INSTRUMENT FOR PASSING A NEEDLE WHERE SPACE IS LIMITED

EVERETT MINGUS, M.D.
MARSHFIELD, ORE.

For the purpose of passing a needle and ligature where the space is limited, such as the back part of the mouth, the base of the bladder in suprapubic operations, or similar situations, I have devised the instrument shown below.

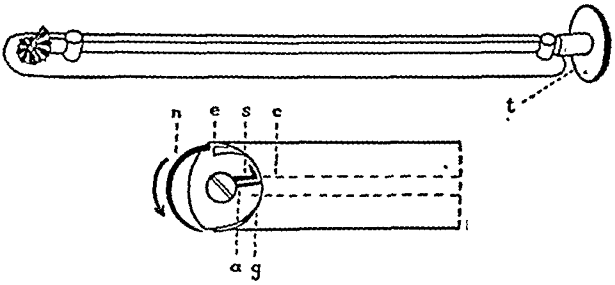

Diagram of instrument for passing a needle where space is limited.

A thread semicircular needle is lodged in a semicircular overhanging guide at the bottom of the instrument; it is propelled forward by a radius arm and held in place by a compression spring and discharged through an eye in the forward end of the guide. The radius arm is driven by a shaft connected with a right-angle cog movement on the back of the instrument. The cog movement is driven by a shaft connected with a milled head thumb-piece at the top of the instrument. The whole is mounted on a flat frame-piece and can be made any size to suit the necessities of the situation. In the diagram, *g* represents the guide; *a*. the driving arm; *s*, the spring; *c*, the eye in the forward end of the guide; *n*. the needle; *t*, the milled head thumb-piece; *c*, the shaft extending from the milled head to the cogs. The arrow to the left of the instrument shows the course the needle takes after leaving the instrument. The needle is engaged in the instrument by introducing the point into the eye of the guide, when the remainder falls readily into place with the butt end resting against the distal end of the driving-arm. Bringing the arm around 180 degrees, by turning the milled head, discharges the needle and causes it to pass through the remaining 180 degrees of the circle; it is now free from the instrument (*n*). If the driving arm is given a slight backward turn to prevent the thread from catching between the eye of the guide and the arm, the instrument is now withdrawn from the field of the operation, and the forward end of the needle is grasped with an ordinary needle-holder, and by a rotary motion in a manner to complete the circle. When the needle is placed in the holder, care should be taken to see that the thread is not entangled with the spring, otherwise there might be some difficulty in getting the ligature to slip through the eye of the guide, when the instrument is withdrawn from the wound. The direction kept by the needle is on a plane with the instrument, and it passes through the tissue with much ease. Truax, Greene & Co., of Chicago, have made this instrument for me in a neat and well proportioned manner.

MICROSCOPIC DIAGNOSIS OF RABIES

A MODIFICATION OF VAN GIESON'S METHOD FOR STAINING THE CHARACTERISTIC NERVE CELL INCLUSIONS

S. B. MOON, M.D.
Director Pasteur Institute of Virginia; Associate Professor of Histology and Embryology, University College of Medicine
RICHMOND, VA.

For several years, in the laboratory of the Pasteur Institute of Virginia, a modification of Van Gieson's well-known method of staining for the diagnosis of rabies has been practiced. It consists essentially in the use of acetone as a solvent for rosanilin in the place of alcohol. When the solution of rosanilin in acetone is diluted with water, the stain yields itself so readily to the affinity of the cell inclusions that heat is unnecessary, as when alcohol is employed, and the inclusions are quickly tinted a brilliant rose-red color.

Furthermore, the stain may be very quickly prepared, should no fresh solution be at hand, rosanilin being extremely soluble in acetone. Nor is it necessary to wait till the solution becomes saturated, though it is preferable to keep such a solution on hand if the stain is used often. The concentrated solution is more stable than that in alcohol, and hence need not be freshly prepared so often. In our laboratory it is preserved in the ice-box, and keeps well in hot weather for a month or longer.

As in Van Gieson's original method, alcohol is used as a fixing agent, and methylene-blue for counterstaining. The modification makes no difference in the results obtained, a sharp contrast being presented between the rose-red cell inclusions, the orange-red blood-cells, etc. It is believed that the readiness of the acetone solution to give up the stain, enables one to detect the inclusions more certainly in brains of animals long dead, when post-mortem or other changes render them more difficult to color. This conclusion is based on practical comparative tests of the two methods.

The following technic is commonly employed in our laboratory:

Smears containing pyramidal cells of the hippocampus, or Purkinje cells of the cerebellum, are prepared in the usual manner, allowed to dry, and fixed for two minutes in ethyl or methyl alcohol. They are then dried with blotting-paper and stained.

Two or three drops of a saturated solution of rosanilin in acetone (U. S. P.) are added to 10 c.c. of water, which is agitated with the pipette, and soon becomes a brilliant rose-red color. Then two drops of a half-saturated aqueous solution of methylene-blue are added, and the stain is applied to the smears.

Staining is completed in one or two minutes, without heat. The slide is then washed under the tap, dried, and examined.

Should a weaker than saturated solution of rosanilin be employed, it is only necessary to add more of it, drop by drop, to the water, till the usual brilliant rose-red tint is obtained, when the result will be found about the same as that obtained with the saturated solution.

AQUEOUS SOLUTION OF IODIN IN THE TREATMENT OF ULCER OF THE CORNEA

A PRELIMINARY NOTE

E. L. MEIERHOF, M.D.
NEW YORK

At the New York Eye and Ear Infirmary we have for a number of years been using, as a routine measure in the treatment of ulcers of the cornea, a solution of mercury bichlorid with a fair amount of success, the patient instilling three to five drops three times daily, and in addition using an ointment of mercury bichlorid once or twice daily. Occasionally a 20 or 25 per cent. solution of argyrol is used in the early stages of the ulcer, especially where the secretion has a tendency to be mucopurulent. In the Morax-Axenfeld infection, with an erosion of the cornea, zinc sulphate is employed. Occasionally phenol (carbolic acid), or other forms of cauterizing, are employed when the ulcer has a tendency to be deep or is spreading. I have also followed practically the same routine in my private practice, but have not been entirely satisfied with it, in spite of additional measures, such as warm bathing, dionin, atropin, etc., except in cases in which syphilis was the principal factor.

Some six months ago, however, I commenced using a watery solution of iodin in these cases, being influenced to do so by the wonderful effect of tincture of iodin in sterilizing raw catgut. The use of iodin in infected lesions of the cornea is not new, but the method heretofore employed was not satisfactory. It was generally used by occasionally touching an ulcer with tincture of iodin, which is extremely painful unless cocain is first employed; and this is sometimes undesirable on account of the desiccating influence of cocain on the corneal epithelium, diminishing the resistance of the corneal tissue to further infection. (Holocain, however, does not have this influence.) I had already used iodin locally in other conditions and obtained very satisfactory results.

The patients suffering from ulcer of the cornea were treated with a solution of iodin 1 grain, sodium iodid 3 grains, and 1 ounce of water. Three drops of this solution were ordered to be instilled into the eye, three or four times daily. No other treatment was used. The cases treated were largely superficial erosions; five of them were ulcers in connection with trachomatous pannus, and several had been previously treated. The instillation of the above mentioned solution of iodin is not very painful, and the duration of the pain is not more than ten or fifteen minutes. Occasionally the conjunctiva becomes congested from its use, but this disappears when the application is stopped. After twenty-four or forty-eight hours of this treatment, the patient will tell you that his eye is less painful and more tolerant to light, and the headache, so common in these cases, diminishes rapidly. The solution can be used for several weeks without causing any further annoyance, even if the ulcer is healed. Altogether, I have treated fifteen patients by this method, and I have been so encouraged by the results that without waiting for the accumulation of further experience I take the liberty of offering it as an addition of great utility to our ocular therapeutics.

Special Article

NINTH ANNUAL SUMMARY OF FOURTH OF JULY INJURIES

For the ninth consecutive year THE JOURNAL this week presents statistics of injuries received during the celebration of the Fourth of July, with particular reference to tetanus resulting from these injuries. Special effort has been made to secure reliable data and all serious cases have been carefully investigated, so that, so far as the statistics go, dependence may be placed on them. In addition to the usual reports, blanks were sent to a large number of hospitals and thousands of letters were sent to health officers and physicians in all parts of the country asking for reports. In fact, unusual effort was made this year to obtain full and complete returns.

In previous years from the hospitals long lists of injured were received, but this year a large majority reported none injured and those which did report cases had comparatively small lists. The reduction in the number of casualties this year was very marked. Our thanks are due to health officers, hospital superintendents, physicians and others for the careful reports which have made these statistics practically complete and the figures reliable. The data are presented in the same manner as heretofore so that comparisons with the figures of previous years may be made.

SANITY VS. GUNPOWDER —By De Mar
[Courtesy of *Philadelphia Record.*]

FEWER CASES OF TETANUS THIS YEAR

There were only eighteen cases of tetanus this year, fifty-four less than last year, and the lowest number reported during the nine years THE JOURNAL has been gathering these statistics. Last year there were seventy-two cases, and 150 in 1909. It is a significant fact that the number of blank cartridge wounds shows a correspondingly large decrease, from 450 last year to 169 this year (Table 6). The most common cause of the wound is the blank cartridge, and the most common site is the hand. Of the twenty lockjaw patients all but one were males, and all but three were under 18 years of age. The youngest was 4 years old, the oldest was 40, and the average age this year was 14 years.

The duration given in the table is the number of days between the time of the injury and death or recovery. Figures are also given (in parentheses) showing the number of days following the injury before active symptoms appeared. This was five to fifteen days, the average for fatal cases this year being about eight days. A longer incubation period probably indicates a less virulent infection and, therefore, a better chance for recovery under treatment. Following the appearance of the symptoms, death resulted in from two to three days; the average of all cases this year, for which this information was given, was two and one-third days. In only one case was the entire time between inoculation and death less than five days, the duration of this case being four days. The average duration for all fatal cases reported was about nine days.

USE OF ANTITOXIN

So far as reports were received tetanus antitoxin was employed in seven of the eighteen cases reported this year, but in no instance, according to the reports, was it employed until after the active symptoms had set in. This is unfortunate, as tetanus antitoxin is so valuable as a prophylactic that very few cases have ever been reported in which active symptoms began after its administration. The list of tetanus cases is given in Table 1.

DISTRIBUTION OF TETANUS

Tetanus occurred in ten states this year, seven less than last year, fourteen less than in 1909, and nine less than in 1908. Three cases each were reported for Illinois and Ohio, and two each for California, Michigan, New Jersey and Wisconsin. Four states, Iowa, Massachusetts, New York and Pennsylvania had one case each. The greatest reduction below last year's record was in Pennsylvania which had 10 cases less than last year followed by Michigan with nine cases less than last year.. Illinois had eight cases less and New Jersey seven less. Table 2 allows comparison of the number of cases in each state for the nine years.

THE DEADLY BLANK CARTRIDGE

Blank cartridges continue to be responsible for the great majority of tetanus cases, 15 or 83 per cent. this year being due to that cause as compared with 88.9 per cent. last year, and 86.5 per cent. in 1909. With the full knowledge of the awfulness of the deaths caused by blank cartridge wounds it is certainly inexcusable that the use of these instruments of torture is not absolutely prohibited. Two cases of tetanus this year were due to injuries by fire-crackers and one by a bomb. The causes of the tetanus cases from Fourth of July injuries for each of the past nine years are shown in Table 3.

THE MORTALITY PERCENT.

Of the eighteen cases of tetanus from Fourth of July injuries this year ten, or 55 per cent., ended fatally as compared with 93 per cent. last year, 84 per cent. in 1909, and 72 per cent. in 1908.

TETANUS FROM INJURIES NOT CAUSED BY FIREWORKS

Besides the cases of lockjaw due directly to the use of fireworks, it is interesting to note also those occurring during the Fourth of July season which were due to penetrating wounds from other causes, such as nails or splinters, to crushing injuries, etc. There was likewise a marked reduction in these cases, only twenty-nine being reported during the Fourth of July season this year, or less than half the number of last year, when forty-seven were reported. Is this reduction due to the prophylactic use of tetanus antitoxin? The cases of tetanus due to other than Fourth of July injuries are shown by states in Table 4. A comparison of this table with Table 2 is interesting.

DEATHS AND INJURIES NOT CAUSED BY TETANUS

Beside the ten deaths due to tetanus, forty-seven persons were killed by various forms of fireworks, making a total of fifty-seven deaths, seventy-four less than last year, and 158 less than in 1909. This is the lowest number of deaths from such causes during the nine years covered by THE JOURNAL'S statistics, and shows a very decided improvement over previous years. This year eleven people were killed outright by firearms, nine by explosions of powder, bombs or torpedoes, five by cannon, two by giant firecrackers and eight by various causes, as blood poisoning, explosions of chemicals, etc. The largest number of deaths due to any one cause was twelve, mostly little girls, who were burned to death by fire from fireworks, in several instances from the so-called "harmless" varieties, including very small firecrackers and sparklers. All accidents not due directly to the discharge or handling of fireworks or other means of noise production and display on or about the Fourth of July have been omitted. Table 5 shows a comparison of the causes of death aside from tetanus for the past seven years.

1911	11	12	9	2	5	8	47

DISTRIBUTION OF INJURIES

In Table 6 will be found a summary of all injuries including tetanus and of all causes arranged by states. Beneath the totals at the bottom are given, for comparison, the totals for the eight previous years. The grand totals for the nine years are also given. Table 7 allows of comparisons of the total deaths and accidents for nine years. The decrease in the number of injuries is most remarkable this year and unquestionably is the result of the efforts to secure more intelligent methods of celebration. This is evident from the fact that the most marked decreases are in the states where the agitation for restrictive measures was strongest. Massachusetts this year had less than one-half of the injuries it had last year and only one-sixteenth of what it had in 1909. Connecticut reduced its total to less than one-fifth and Minnesota and New Jersey reduced their totals to one-fourth what they were in 1909. Other states showing marked reductions are Indiana, Iowa and Michigan.

Pennsylvania has had the largest number each year since 1904, having 442 casualties this year, followed by New York with 237, and Illinois with 217. Note that two years ago the same three states had respectively 986, 897 and 546 injuries. Altogether there were 1,603 injuries this year, a little more than half of last year's record and less than one-third of the totals for 1909.

NATURE OF NON-FATAL INJURIES

There were 1,546 non-fatal injuries this year, a little more than half (55 per cent.) of the total reported last year. Eight persons were totally blinded this year, twenty-six lost one eye each, thirty lost legs, arms or hands, and eighty-three lost one or more fingers. Considering the marked reduction in the total number injured it is surprising to note that the totals of these more severe injuries are about the same as reported last year. The giant firecracker continues to hold the first place as a cause of mutilating wounds and is responsible for most of the losses of eye, hands and fingers. This year 483 injuries including two deaths and two cases of lockjaw were due to the giant firecracker. Firearms caused 184 accidents this year including eleven killed. Of the total number thus injured, eighty were struck by stray bullets from the reckless use of firearms by others, and six deaths resulted. The use of the toy cannon caused 114 injuries including five killed, but this year caused no cases of tetanus. In the nine years a total of 39,129 people—the equivalent of over thirty-nine regiments—were killed or injured in the celebration of the Fourth of July!

TABLE 7.—TOTAL DEATHS AND ACCIDENTS BY STATES DURING NINE YEARS

TOTALS IN CHIEF CITIES

Table 8 shows the number reported killed and injured in our largest cities during each of the past five years. The population figures are from the United States Census of 1910. This table is of particular interest since by it the results of the adoption and enforcement of prohibitive or restrictive ordinances can be seen. Sometimes, however, although very small numbers of injuries are reported, more deaths occurred than in other cities having more injuries. New York City reported three deaths, the largest number this year, Chicago reported two, and eleven other cities reported one each, making a total of sixteen deaths in our eighty-four largest cities as compared with forty-three killed last year, eighty in 1909, eighty-three in 1908 and ninety-four in 1907. Although Philadelphia is the one large city having more than 100 injured this year, it is the only time in the last five years that no deaths are reported. Only 771 non-fatal injuries were reported for these large cities this year as compared with 1,455 last year, 2,935 in 1909 and 2,860 in 1908. A marked reduction is seen in the records of practically all these cities, even Philadelphia having reduced its total by one-fourth.

Of these eighty-four cities, sixty-three have a record of five or less injured this year as compared with thirty-seven last year, twenty-six in 1909 and twenty-three in 1908. There were twenty-four of these cities having a clean record this year as compared with eighteen last-year and only ten in 1908. On the other hand, only one city this year had a hundred injured, as compared with three last year, six in 1909 and six in 1908. Probably the most remarkable reductions in the last few years have been at Milwaukee, which records a fall of from 112 in 1910, to nineteen in 1911; at Boston, which records a fall from 190 in 1908, to only three in 1911, and at Newark, N. J., a fall of from 150 in 1909, to none in 1911.

WHERE THE RESPONSIBILITY RESTS

The responsibility for the vast majority of Fourth of July injuries clearly rests with city governments, since the employment of death-dealing methods of celebration is subject to their regulation. It is, therefore up to the city governments to decide whether or not the maiming of thousands, the agonizing deaths from lockjaw and the burning to death of little children by fire from fireworks are to be continued. Prohibitory ordinances are most effective and permanent, as shown by the results in Baltimore, Washington, Cleveland, Trenton and other cities, and even restrictive ordinances, if enforced, are quite effective, as shown by the results in New York, Boston, Chicago, Toledo and elsewhere. But the enforcement of restrictive measures is more difficult and requires more constant vigilance on the part of the police. By the sound, it is difficult to know whether an explosion is due to a firecracker 3 inches long or to one 5 inches long or whether it is due to some other forbidden form of fireworks, while under a prohibitory ordinance any explosion would be recognized at once as a violation of the law. Again, the smaller firecrackers, which have been considered so harmless, caused the clothing to catch fire in several instances this year, most of these being girls and young children, who were burned to death. Even the "harmless" sparkler caused some of these deaths which were far more agonizing than if caused by gunshot wounds.

RECENT PROGRESS

It has been well understood that the obliteration of the sorrow and suffering needlessly caused during the annual celebration of the Fourth of July could be brought about only by a vigorous campaign of education favoring more enlightened methods coupled with the enforcement of restrictive or prohibitive legislation against destructive methods. The Journal has been doing what it could for nine long years and apparently with small result until gradually more attention was given by prominent periodicals and newspapers. A campaign for more sane methods was started which, during the last three years particularly, has been most vigorous. Not only has the press of the country largely taken up the cause, but also local, state and national societies. They have not only argued against the use of fireworks, but, more important still, have provided more rational and patriotic means of celebration. A correspondingly vigorous action has been taken by city councils during the last few years in enforcing restrictive or prohibitive legislation. These forces, using and quoting as they did the statistics of the awful results of the old-time methods, as published annually in The Journal, have finally reduced the totals of casualties to a small fraction of what they were in previous years. The necessity of perseverance in this campaign for better methods of celebration is aptly shown this year by the record of Philadelphia. In spite of a most vigorous campaign which was carried on in that city this year, the results seem to be comparatively small, that city still having over 200 injuries. A continuance of that campaign, however, will doubtless prove more effective. The enforcement by the city authorities of restrictive measures, similar to those adopted by Chicago, Boston, New York and elsewhere would do much to help the situation. Reports indicate that hundreds of smaller cities and towns this year enforced either restrictive or prohibitive measures.

THE METHOD OF SUBSTITUTION

Better by far than the negative methods of restricting or prohibiting the use of fireworks this year, however, was the more general adoption of positive methods of reform. Our national Independence Day should cease to be a day of destruction and become a day of joy, of recreation and of enlightenment. From every section of the country comes the news that, in place of the senseless din of former years, more truly patriotic methods have been employed. The music of bands, the children's parade, the witnessing of historic floats, and afterward the picnics, the trips to the parks or the visiting of friends—these methods were employed more than ever before. And the result is very evident: the smallest number of lockjaw cases and other deaths reported in any year since The Journal began the collection of these statistics, fewer destroyed eyes, fewer maimed bodies and an astonishing reduction in the number of injuries. Let the campaign be continued until common-sense methods of celebration shall prevail throughout our fair land!

Crepitus.—The letters composing this word, used as the initial letters of an acrostic, says Dawbarn in the *Medical Record*, help us to remember the signs of fracture:

Crepitus.
Roentgen rays, fluoroscope, etc.
Ecchymosis.
Percussion, osteophonic.
Inability (disability).
Tenderness and pain.
Unnatural mobility.
Swelling, shortening, or other deformity.

Therapeutics

ANTERIOR POLIOMYELITIS: INFANTILE PARALYSIS

The picture of a child suffering from more or less weakness of one of its limbs, which on examination is found to exhibit atrophy of a particular group or groups of muscles, is familiar to every practitioner. This condition was designated as infantile paralysis.

During the last twenty years infantile paralysis has been observed repeatedly in epidemic form. The prevalence of the disease has greatly increased, in epidemics especially, and it has consequently received an increasing amount of investigation, both of its clinical and pathologic features.

Previous to the recognition of its epidemic occurrence, it was described as a disease of the spinal cord affecting chiefly the motor cells of the anterior horns of gray matter. It was considered by some pathologists that the degeneration of these motor cells was the primary lesion. By others it was considered that the cell degeneration and atrophy was due to a congestion and inflammation of the interstitial structures of the spinal cord. After it began to be realized that the disease occurred in epidemics, the opinion gained ground that the disease was of an infectious character, due to the action of some specific poison, and not a local inflammation or nerve degeneration due perhaps to climatic influences or to some autogenous poison, the character of which was undetermined. It is now believed that poliomyelitis in an acute infectious disease which affects chiefly the central nervous system, which may affect the brain as well as the spinal cord, and which may affect the white matter and the meninges as well as the gray matter.

The occurrence of the disease in epidemics has naturally raised the question as to whether it is contagious. Much evidence has been presented in favor of this theory. It has been asserted that the disease is directly transmissible from a patient having it to another with whom he comes in contact; that it may be carried by a third person from the person who is sick to a person who subsequently becomes sick; and that in many cases in which the direct transmission has not been recognized, it has really occurred through one who has been designated as a carrier, who may be a person who has suffered a slight or abortive attack of the disease which has not been recognized.

While these different methods of transmission have been advanced and discussed, it must not be forgotten that a very large number of people who come in contact with the patient suffering from the disease do not contract it. This may be due to some immunity to the disease which is not at present understood, or to the slightly contagious character of the disease.

In most epidemics more than 80 per cent. of the cases have occurred in children under 10 years of age, although a few cases have been observed in adults. Its occurrence in adults is not new, as occasional cases were reported before the epidemics were observed.

The mortality varies from 3 to 30 per cent., according to the severity of the particular epidemic.

The manner in which the contagious element is received has not been definitely established. There seems to be considerable reason for believing that the secretions from the nose and throat contain the contagious element, and that this may be received into the corresponding organs of the individual who contracts the disease. In some epidemics it has seemed that the disease was carried by dust, and it has been proposed to limit the spread of the epidemic by watering the streets. Some observers have implicated the common house-fly as a carrier of the contagion, and while the transmission of contagion in this way seems possible, it is difficult at the present time to prove definitely the culpability of this insect.

The disease occurs more frequently during the warm months of June, July, August and September. The period of incubation has been found to vary from three to thirty days, but is usually from eight to ten days.

The character of the contagious element of the disease for a long time baffled the bacteriologists. Within the last year or two it seems to have been determined with reasonable probability that this is a microorganism much smaller than those which have hitherto been determined to have an important part in the causation of disease. This particular organism is so very small that it can be detected only with the greatest difficulty by the most powerful microscopes. It is so small that it passes through filters which have hitherto been relied on to obstruct entirely the passage of pathogenic organisms. That it is a living organism capable of reproduction seems probable from the fact that very small quantities of the toxic element suffice to produce the disease experimentally in the lower animals, and particularly in the monkey, and that the disease may be transmitted through several successive monkeys.

The effect of this poison on the human individual varies very greatly. The typical lesions, as already stated, are found in the spinal cord, and consist of the changes characteristic of congestion and inflammation. These are a proliferation of the cells about the blood-vessels, with a narrowing of their caliber, and edema in the interstitial substance of the gray matter of the cord. These vascular changes, while most marked in the gray matter of the cord, are seen also in the white matter and in the meninges. The degeneration of the motor cells of the gray matter seems to be secondary to these congestive and edematous changes. Changes of similar character are found in some cases in the brain. The effects of the disease are also observed in the lymph-glands and spleen. The parenchyma of the heart, liver and kidneys shows cloudy swelling.

The symptoms of the disease are those of a general infection with localization in the nervous system. The general symptoms precede the peripheral manifestations of the affection of the nervous system. They are fever, which may be accompanied or preceded by restlessness, irritability and insomnia, or in some cases by restlessness and indifference. There may be convulsions, headache, pain in the back and limbs. Where the severity of the disease is not so great as to cause convulsions, there may be twitchings of the limbs and symptoms of meningeal irritation of the brain and cord. The digestive organs may be disturbed, and there may be vomiting and diarrhea. In other cases constipation is present. Sometimes sweating is a prominent symptom. After these general symptoms have lasted from twelve to seventy-two hours, the characteristic peripheral symptoms appear. These consist of a weakness, or complete paralysis, of certain groups of muscles in one or more of the extremities. Usually no impairment of power is noticed until there is complete paralysis of motion. Sensation is usually unaffected. The loss of motion is accompanied by impairment of the reflexes. If a lower extremity is affected, the patellar reflex of that limb is absent. In severe cases all of the limbs may be affected, and the paresis may advance upward until the muscles of speech, of deglutition, and finally of respiration are affected, the latter usually resulting quickly in death. Where a single limb is affected, the paralysis, after a few days, may gradually diminish, and in a few weeks the power of the limb may be entirely restored. In other cases there may be little change for four or five weeks, when the patient may gradually regain strength, but this improvement, after continuing slowly for several months, may entirely stop, short of complete recovery. The general symptoms usually entirely disappear within a week. There is not, in ordinary cases, interference with the function of the bladder or rectum.

The resulting paresis may be followed by great impairment of the usefulness of the limb, and in many cases by considerable deformity, and, especially when the lower limb is affected, by various forms of club-foot.

The diagnosis is not usually suspected when the patient is first seen, unless at that time paralysis has already intervened and is called to the attention of the physician. When the existence of an epidemic has been recognized the physicians in a locality are more alert to detect cases of the disease, and as a rule the diagnosis is made earlier. Under these circumstances, indeed, the physicians not infrequently err in diagnosticating the disease when some other disease is present.

A search is still being prosecuted for a serum which will cure the disease or cut short its course and prevent its more serious effects. The discovery of such a serum would give increased importance to the early diagnosis of the disease, and efforts have been made to find some method of making a correct diagnosis of the disease before the appearance of the paralysis. The blood has been examined very many times, but no definite change in it has been found, except that generally there is a so-called leukopenia, a diminution in the number of white blood-cells. The cerebrospinal fluid has also been examined in many cases. When the disease is fully developed this fluid shows very little change. There may be a slight increase in the intraspinal pressure, but the fluid is clear. It may contain an increased number of leukocytes, but does not contain bacteria. These findings enable one to distinguish the disease from epidemic cerebrospinal meningitis or from tuberculous meningitis, if the presence of either of the three diseases is suspected, but the early symptoms of poliomyelitis are so like those of many illnesses of childhood, which are of not great importance or significance, that one would hardly be sure of making an early diagnosis of every case of poliomyelitis. Practically, except in the presence of a recognized epidemic, it is difficult, if not impossible, to make the diagnosis of the disease before the occurrence of the peripheral paresis, and as this may be delayed for three or four days, the diagnosis will usually remain in abeyance for several days after the child is taken sick.

Before the peripheral paresis occurs, the disease for which it is most likely to be mistaken is cerebrospinal meningitis. From this disease it may usually be distinguished by the absence of the pain in the back and of rigidity of the muscles of the neck, by the early discontinuance of vomiting, by the absence of impairment of intelligence, and by the absence of Kernig's sign. In adults it may be mistaken for multiple neuritis. Here the more complete paralysis and the rapid wasting of the muscle are important diagnostic signs.

TREATMENT

As already stated, although the search for a serum is being assiduously prosecuted, it has not been definitely determined at the present time. It is, therefore, necessary to rely on general and symptomatic treatment in combating the disease. Perhaps the one measure of treatment on which all writers now agree as being important, is absolute rest. The child should at once be placed in bed and kept quiet, as should all sick children. Following the treatment generally recognized as useful in all infectious diseases, the first medicinal treatment to be prescribed should be a laxative. Probably nothing is more useful than 2 grains of calomel (this for a child 3 years of age), although some prefer the administration of a saline laxative, and still others, castor oil. If vomiting is an important symptom, the calomel will usually be found easier of administration and more satisfactory in action. Elimination may also be promoted by a diuretic, than which none is more useful than 5 grains (0.30 gm.) of citrate of potassium, repeated every four hours—this also for a child of 3 years. If the skin is hot and dry, a diaphoretic may be employed. For this perhaps nothing is more useful than a white woolen blanket wrung out of hot water and wrapped about the child, and outside of this is placed another woolen blanket. This hot pack should not be long continued. Perhaps as valuable is a hot bath or hot sponging.

If the pains are moderately severe, the salicylate of sodium may be given in doses of 2½ grains (0.15 gm.) repeated every two hours, for a child of 3. If the pains are severe, it may be necessary to give opium in some form. This is best administered as the tincture of deodorated opium; one drop, in water, every two or three hours, as needed.

The fact that hexamethylenamin has been found to be eliminated in the cerebrospinal fluid has led to the recommendation of this drug in poliomyelitis. It is highly recommended by some writers who have used it, and as unhesitatingly condemned by others. It is a harmless drug, however, and may do some good. The dose for a child 3 years old is 3 grains (0.2 gm.) every six hours.

Finally, it remains to consider the use of drugs directed toward combating the local lesion of the disease. Considering that congestion, inflammation and edema are found in the spinal cord of patients who have died of this disease, it has been recommended to give ergot, on the theory that this would contract the vessels and diminish the congestion and counteract the edema. It must be remembered, however, that while the vessels show marked cellular proliferation, they are not dilated, but on the other hand, the cellular proliferation often leads to narrowing of their caliber, and some observers have found thrombi within them. But in spite of these facts, not a few believe that ergot is indicated, and that its administration is followed by improvement in the symptoms. This drug may be discontinued when the acute symptoms have subsided, and then the question arises of giving some drug which will remove the products of the inflammation. For this purpose no drug can be more useful than an iodid; but the use of an iodid for this purpose is condemned by many as useless. Small doses, as 1 grain (0.05 gm.) three times a day can do no harm and may be of value.

The application of counterirritants over the spine has seemed to many clinicians to be productive of good, but this measure has been condemned by others.

Recollecting the congestion which is observed, some advise that the child should not be allowed to lie continuously on its back, but should be made to lie first on one side, and then on the other side; but here the opinion of the profession is not a unit, many advising that the child be kept on the back. It seems good sense, however, to change the child's position.

Ice-bags to the head and spine have been advised by some, and as vehemently condemned by others. As children bear ice applications badly, it seems more sensible to relieve congestion of the central nervous system by hot sponging and hot foot baths with the patient reclining.

While treating the acute stage of the disease, one must bear constantly in mind the disastrous after-effects which are likely to follow, and must use every method available in the endeavor to prevent these. When the muscles become paralyzed, great care should be taken to maintain the limbs, especially the legs, in such a position that the affected muscles will not become overstretched and that the unaffected muscles will not become overactive so as to draw the limb into a distorted position. This may be accomplished by elevating the clothes so that the weight of them will not press on the limbs, and by putting sand-bags around the limbs in such a way as to counteract the tendency to abnormal displacement.

After the acute symptoms have subsided, the treatment must be directed to the affected muscles. It is an important question how soon the treatment of the muscles should commence, and what measures should be adopted. As the motor nerve-cells are destroyed or at least temporarily impaired the muscles are deprived of their natural motor control. While one is waiting for the restoration of the nerve-cells, if it is to occur, the nutrition and contractility of the muscles must be maintained. For this purpose nothing is better than galvanic electricity, which should be applied gently to the paralyzed muscles, daily for ten or fifteen minutes, with the negative pole active. This will improve the motility of the part and maintain its contractility. Massage should also be given, but this should be gentle and not severe, and care should be taken not to damage the nerves in the vicinity of the muscle by undue force. In three or four weeks the patient should be encouraged to make voluntary movements of the affected muscles. If the use of the muscles is very greatly impaired, much benefit will be found from placing the patient in a warm bath at a temperature of 100 to 104 F., which must be maintained while the patient is in the bath. The water surrounding the limb on all sides helps to counteract the force of gravity in drawing it out of the proper position. The movements, when they are feeble, are also more easily accomplished in the warm bath. A system of muscular education should be undertaken with the patient, and he should be taught and encouraged to move the different muscles as far as he is able, and he should be coaxed to do this without having it impressed on him that he is moving his muscles, but rather he should be deceived into thinking that he is playing a game or doing some athletic exercise which interests him aside from the muscular movement.

It used to be the custom to advise and to give strychnin even in large doses soon after the symptoms of paralysis developed. It was then given for many months, at least as long as any improvement occurred. Most clinicians now, however, believe that strychnin should not be given. Theoretically the facts would be these; that while the inflammation was active, strychnin would certainly be contra-indicated. Also, if strychnin caused the child to be irritable, restless and nervous, even if given in small doses, if it caused the child's heart to become irritable or rapid, it certainly is contra-indicated. On the other hand, five or six weeks after the onset of the disease, a test of strychnin for a week to see if it would stir up the motor excitability of the spinal cord to the point of improvement, is perhaps advisable. If its action is for good, it could be continued; if it causes undesirable symptoms, it should be stopped.

The treatment by electricity, massage, and systematic exercise should be continued for from six to eighteen months. When, after the expiration of such a period, the patient has been at a standstill for a month or two, the propriety of orthopedic treatment should be considered. This varies from the adjustment of braces to bloodless and bloody surgery. Unquestionably great harm has been done by the application of heavy braces to patients suffering from infantile paralysis; but, on the other hand, there are a certain proportion of patients who are benefited by a light and well-fitting brace. This should not be used to such an extent that the patient will not get an adequate amount of exercise with the affected muscles. Unless this is looked out for, harm will be done by the brace.

The transplantation of muscles, which seemed to offer so much hope of benefit to this class of patients through the restoration of muscle balance, does not usually accomplish as much as is hoped for. Nerve anastomosis has accomplished somewhat more satisfactory results, but is often a disappointment. Its object is to effect restoration of power to the affected muscle. It is especially applicable when the muscles of the hand or shoulder are involved.

Tenotomy to counteract the excessive contraction of healthy muscles has sometimes proved beneficial, but the operation should be performed with care, and should only be undertaken in suitable cases. In some cases where there is excessive mobility of a joint it has been proposed to make the joint stiff by an osteoplastic operation. In still other cases, especially about the ankle, the removal of a portion of the bone, especially of the astragalus, has sometimes served to overcome a deformity due to this disease and to increase the usefulness of the limb.

The proper prophylactic treatment cannot be said to be definitely determined, but inasmuch as there is considerable reason for believing that the disease may be directly transmitted from one person to another, and that the contagium may be carried by a well person from one who is sick, it is desirable to insist on strict isolation of every patient affected with the disease.

It may be advisable to have the streets sprinkled systematically in towns where the infection is recognized to be present.

The room where the patient is sick should be carefully screened and flies should be kept away from the patient, for his own comfort as well as to prevent the possibility of their carrying infection to others.

When a community becomes afflicted with a scare of epidemic infantile paralysis, and frightened parents desire to do something to prevent their offspring from becoming affected with the disease, hexamethylenamin may be administered internally, and gargles of 10 per cent. solution of hydrogen peroxid, or other antiseptics, may be advised.

The Pretty Nearly Clean Operator.—Let us never forget that almost invariably if a clean, freshly-made wound fails of primary healing it is because of actual, tangible, visible particles of dirt conveyed therein while operating or subsequently during dressings. Remember this: Few hands, few failures! and this even when the air is dusty.—Dawbarn in the *Medical Record*.

SATURDAY, AUGUST 26, 1911.

A TRIUMPH OF PREVENTIVE MEDICINE

In spite of the human tendency to forget what is disagreeable, most of our readers will recall the surprise and mortification with which the American people confronted the devastating epidemics which swept through the camps of the troops mobilized at the time of the Spanish War, thirteen years ago. It has been, therefore, most agreeable to read the highly favorable health reports which have come from time to time from our troops in Texas, and which have been brought to the attention of the medical profession by the President of the United States in words of hearty commendation.

Now that the Maneuver Division has been abolished by the return of most of its constituent organizations to their stations, it is of interest to be informed from an authoritative source what were the methods of procedure by which the new knowledge of preventive medicine has been applied to camp sanitation, and to have an exact and official statement of the results accomplished. It is impossible to read Colonel Kean's article published in another column of this issue, and especially the remarkable comparative figures at its end, without realizing that an epoch-making achievement in preventive medicine has been accomplished by the Army Medical Corps. For purpose of comparison with the Maneuver Division a table is given showing the typhoid record of a division of volunteer troops camped at Jacksonville, Fla., in 1898 under conditions similar to those at San Antonio this summer. But the difference is amazing. The division of 1898 has 2,693 cases with 248 deaths, which was about the average typhoid incidence of the camps of the Spanish War, while the division of 1911 had one case and no death. The deaths from all diseases were 281 for the former and eleven for the latter.

At the beginning of the Spanish War it was an accepted belief on the part of the medical profession that typhoid epidemics were due to polluted water-supplies and that with pure water this disease was not to be feared, but the experience of that war demonstrated that the question was not so simple and that contact infection, flies and other factors had to be considered. These other factors have been studied with much care in recent years, and it has been found that they can be to a large extent, but not entirely, removed by scrupulous attention to the cleanliness of the camp and the details of personal hygiene among the men.

While the disposal of fecal matters and other wastes seems to have been carried out in this camp with admirable thoroughness of execution and simplicity of method, no new sanitary principle was evoked and we must look further for the explanation of the enormous discrepancy between the amount of typhoid fever in the Second Division, Seventh Army Corps, thirteen years ago and the single case in the Maneuver Division.

It is clear that the medical officers attribute their triumph over typhoid fever to the method of immunization by the injection of dead cultures of the typhoid bacillus which was introduced into the army two years ago as a voluntary measure, and was for the first time made compulsory when applied to the officers and men of this division. The value of this preventive measure, as well as its innocuousness, has thus been demonstrated conclusively and on a great scale. It would seem, therefore, that the time has come for the medical profession throughout the country to follow the example of the Army by making use of the typhoid prophylaxis in general practice. The high degree of efficiency shown by the medical service in the recent mobilization is not fortuitous, but is the fruit of patient, laborious and ably directed efforts to apply the lessons of the Spanish War, and to assure the best results. This efficiency is a legitimate source of pride and satisfaction to the medical profession of the country, and should be a sufficient demonstration to the government of the wisdom of adequate and generous provision for its sanitary service. It is regrettable to read of shortages of officers, of men, and of mules for the sanitary organizations, when only a single division is mobilized.

DEATHS BY DROWNING

This is the season of the year when deaths by drowning are most frequent. Every Monday morning's paper brings its quota. The day after every holiday tells of a like toll of young lives paid for foolishness or accidents that might have been avoided. Usually the victims are in early life and in the very best health, otherwise they would not have taken the chances that prove fatal, and it seems too bad that so often apparently nothing can be done for them. Until well on in September these casualties will continue.

Undoubtedly as the result of old traditions there is in many places too ready acquiescence in the belief that a person who has been under water for five or ten minutes or even fifteen or twenty minutes is necessarily dead. There are well-authenticated records of the resuscitation of persons who had been submerged for half an hour or even longer. Such cases occur particularly in women and children, and the reason seems to be that the fright at finding themselves in danger of drowning actually brings on a collapse or faint in which the heart and breathing stop and they sink, but low-grade life processes continue for a considerable period. Strong men who have battled for their lives and then sunk are not so often revived, though if taken with a cramp they too may suffer from shock or fright with the resultant collapse that is apparently Nature's method of giving the longest possible opportunity for life under these circumstances.

All the recent experience with regard to death from shock or so-called death is extremely interesting in this regard. Patients have been reported as not breathing for fifteen minutes to half an hour and yet they have been resuscitated. The most interesting phase of surgical experience in this regard has been that sometimes when all other methods failed actual rhythmic squeezing of the heart caused that organ to resume its beating. In some of these cases this beating of the heart only maintained itself after the injection of a certain amount of physiologic salt solution into a vein in order to give the heart something to work on more readily.

There would seem to be a question whether some of these methods should not be employed on persons supposed to be dead from drowning. Ordinarily the methods of resuscitation are and ought properly to be exercised at the scene of the accident. Often the person is pronounced dead even before a physician has seen him. Only rarely are such cases transported to hospitals to be treated. There is an unfortunate prejudice among young ambulance surgeons by which ridicule attaches to the bringing in of a patient in whom death ensues without definite signs of life having been exhibited after the patient's reception into the hospital. The ordinary methods of artificial respiration might well be carried on in an ambulance and then in the hospital itself. Recourse might be had to any procedures, even surgical, that seem to give the slightest hope.

Certainly in the present state of our knowledge it would seem that some direct irritation of the heart muscle should be tried before the patient is pronounced dead. The responsibility of surgeons who were operating at the moment when collapse occurred has led to a very thorough development of means of resuscitation for their patients. Unfortunately with regard to the drowned there is no such responsibility and the consequence has been that all of the means at the command of recent surgery have not been applied. The saving of even a few of these young lives would be a very precious advance for modern medicine. The subject deserves the special attention of surgeons.

FOURTH OF JULY CASUALTIES

We present this week statistics showing the number of deaths and injuries resulting from the celebration of the Fourth of July in 1911. It is very encouraging to note a most remarkable reduction in the totals of killed and injured, these being the lowest since 1903 when The Journal began the compilation of these statistics. Of special significance is the great reduction in the number of deaths from tetanus. These reductions are due to an aroused public sentiment favoring saner methods of celebration, and in the creation of this public sentiment the statistics gathered and published by The Journal have had more to do than any other one factor.

Nine years ago The Journal began the collection and publication of these statistics. A year or so prior to that time a few public-spirited newspapers, notably the Chicago *Tribune*, immediately after the Fourth, had published, as a news feature, imperfect lists of the killed and injured. Such lists as were published the day following the celebration were necessarily imperfect. To secure accurate data it was necessary in a deliberate manner to verify the newspaper reports, eliminating those which on investigation were found not to be due to the celebration of the Fourth of July; to obtain reports from hospitals, health officers, physicians and others, of cases which had not been reported by the press and, of still more importance, to include the information regarding those who contracted lockjaw and the deaths which occurred days or weeks following the injury. The compilation of these complete data was begun in 1903 by The Journal, which year after year, has published actual facts concerning the awfulness of the results of our annual Fourth of July celebration; facts showing the agonizing death from lockjaw of hundreds of bright boys and girls; the burning to death of others, mostly girls and little children, and the shooting and maiming of thousands—all this, that we might celebrate the birthday of American freedom! The callous indifference with which the reports were received was disheartening. In 1907, however, in addition to the other figures, the numbers killed and injured for each of the larger cities were shown separately and it was pointed out that the responsibility rested with the city governments. Further, the matter as it appeared in The Journal was reprinted in pamphlet form and these were sent to city officials, to newspapers and to others interested. They were also furnished in quantities to numerous state and civic societies. From that time the change has been marvelous. Newspapers generally began to publish our statistics, and magazines and periodicals took up the cry, urging the adoption of more common-sense methods of celebration and demanding a restriction of the sale and use of fireworks. In this campaign The Journal figures were quoted far and wide, and the expression, "a safe and sane celebration," as opposed to the "barbarous and insane celebration," became familiar to every one. Then several cities, like Toledo, Chicago, New York and Boston, adopted restrictive measures, thereby greatly reducing the casualties, while Baltimore, Washington, Cleveland and Trenton vigorously enforced prohibitory ordinances, with the result that deaths and injuries were reduced to the minimum. And now such restrictive measures have been adopted by thousands of cities, towns and villages throughout the country.

On the other hand, city governments, civic organizations, medical and other societies took up the task of providing better means of celebration; Springfield (Mass.), St. Paul, Detroit, Toledo, Chicago, Pittsburgh and other cities spent thousands of dollars, employed special artists, or adopted other measures, to provide special programs in which music, the display of flags, the marching of soldiers, children's parades and historic floats illustrating natural achievements were prominent features. The results in these cities have been so encouraging and satisfactory that the continuance of such methods and their wider adoption are assured.

This is the day for the merciless exposure, in this country, of low morals, graft and disregard for law which are rife enough in high places and low. It is to be regretted that our national holiday has been largely given over to a furtherance of this apparent decadence in our national life. But an awakened public conscience must not rest with the exposure of wrong-doing; it must establish honesty in place of graft, morality in place of immorality, and love of law and order in place of lawlessness and disorder. And so the forces working for more enlightened methods of celebration should realize that in the use of pageants, military drills and parades with the display of floats representing historic events and national achievements, the Fourth of July is the nation's greatest opportunity to preach the gospel of national and civic righteousness and to point the attention of the youth of our land to the characters who have made and developed this nation and who are worthy of emulation.

The work began by The Journal, therefore, has grown and expanded not only along the line of initiating "safe and sane" methods of celebration but also in the adoption of ordinances which would repress the irresponsible hoodlum and the reckless users of firearms and blank cartridge pistols. And the results in the saving of lives and the prevention of needless injuries have been most gratifying. Injuries have been reduced from 5,623 each year to 1,603; the total of deaths from 466 to 57 and agonizing deaths from lockjaw from 406 to 10—naturally, The Journal feels a satisfaction that its labors have resulted in so much good to the people of this country. But the campaign must not stop. A record of 57 people killed, including ten children tortured by lockjaw and 1,546 others more or less seriously injured as a result of this year's celebration, still reflects too seriously on the conscience and common-sense of the people of our land to permit a cessation of active endeavor until all such needless casualties have been eliminated. The work of reform must go on until the Fourth of July shall cease to be desecrated by disorder and destruction with its aftermath of suffering and sorrow, but shall become as it should be, a day conducive to a stronger love of law and order; to a genuine love for our country and the principles for which it stands.

MALTA FEVER IN TEXAS

On page 730 of this number of The Journal Dr. Ferenbaugh describes several instances of Malta fever developing in Texas. There seems to be no occasion to doubt the correctness of the diagnosis in these cases. They occur under circumstances that are known to be favorable for the development of the disease in question, the symptoms and clinical course are those of Malta fever, and positive agglutinative results are given by the serum of the patients with cultures of *Micrococcus melitensis*, the accepted cause of Malta fever. So far as known this is the first actual demonstration of the indigenous occurrence of this disease in this country. It is true that Colonel Bruce, the discoverer of *Micrococcus melitensis*, states that Malta fever occurs in the Mississippi Valley,[1] but he gives no authority for this statement.

Single instances of imported cases are described by A. A. Smith[2] and Musser and Sailer,[3] and Bruce narrates the following accidental experiment, which played an important part in clearing up some of the problems of the genesis of the disease: In 1905 the S.S. *Joshua Nicholson* shipped sixty-five goats at Malta for export to the United States. The milk was drunk by the captain and many of the crew, with the result that an epidemic of Malta fever broke out on board the vessel, almost everyone who drank the milk being infected. Even after the goats reached America and were placed in quarantine, a woman who drank some of their milk had the fever.

Now that the disease has been shown to occur in Texas, it would not be strange at all if it should be found that it is more widely spread than has been apparent, in all probability masquerading, like so many other febrile diseases, under the names of hitherto better-known fevers. Its demonstration in Texas at this time is another illustration of the great advantage and power of applying modern methods of investigation to clinical problems "in the field" so to speak, and it is a matter of considerable gratification to note that for this kind of work the medical officers of the army appear to be especially well equipped.

It may be recalled that Malta fever is a disease of long duration, characterized by continued fever, profuse perspiration, constipation, frequent relapses ("undulant fever"), rheumatic or neuralgic pains, swelling of joints, or orchitis. Its recorded history is brief and the important discoveries to which we owe our present knowledge about it have been made by British army medical officers. The first thorough clinical description was written by

---

1. Bruce, D.; Malta Fever, Modern Medicine, iii, 17. This is an excellent account of the disease and should be read by all who wish to review the facts concerning it. See also Hughes, M. L.: Mediterranean, Malta, or Undulant Fever, 1897.
2. Smith, A. A.: A Case of Levant Fever, Tr. Assn. Am. Physicians, 1897, xii, 414; also Am. Jour. Med. Sc., 1898, cxv, 50.
3. Musser and Sailer: A Case of Malta Fever, Phila. Med. Jour., 1898, ii, 1408, and Tr. Assn. Am. Physicians, 1899, xiv, 163.

Marston in 1861; in 1887 Colonel Bruce discovered the specific bacterium *Micrococcus melitensis;* in 1897 Wright and Semple applied the method of serum agglutination to the diagnosis of the fever, and since 1904 the commission formed under the auspices of the Royal Society of London has made valuable contributions to our understanding of its mode of spreading, the most important being that goats may harbor the cause of the disease in their blood without being themselves manifestly ill, and that the micrococcus leaves the body in the milk, thus affording adequate explanation of many features in the epidemiology of the disease as well as a basis for preventive measures. In human beings the micrococcus is excreted in the urine in a considerable proportion of cases and this may be a means of conveying the disease from place to place as well as of local dissemination.

Current Comment

A POSSIBLE SOLUTION OF THE STORAGE EGG PROBLEM

Under the Food and Drugs Act some of the cold storage people have been much exercised by the regulation requiring that eggs shall not be stored longer than three months before using. They assert not only that it is impossible to keep all of their stock moving within that length of time, but that it is not necessary, as the eggs do not deteriorate sufficiently in that time to make them dangerous or undesirable as a food. Egg dealers have also been accused of removing bad eggs from the shells, canning them, using various preservatives, and selling them to bakeries to use in their baking operations which, of course, would be in violation of the Food and Drugs Act. Attempts have also been made in this country, we believe, to desiccate the egg but probably without great success, as the industry has not attained great proportions. In German China, however, according to the report of Consul J. C. McNally at Tsingtau, the desiccation of eggs is successfully carried on and the product is shipped in large quantities to Germany. One shipment has also been made to the United States with the expectation that the eggs *will* comply with the Food and Drugs Act and that a thriving trade may be built up with this country. The nature of the machinery and the exact method employed in making these dried egg products are held secret. The eggs are carefully candled, the fresh ones are washed and opened and the yolk separated from the white. With the aid of a suction pump the yolk is drawn from a tank through a large pipe into a vacuum in the machine and is dried in fifteen seconds. It is then passed on to a larger receptacle into which the material falls in the form of flakes, which look clean, have a good color and a fresh odor. The flakes are again passed through a machine and come out in a powdered form ready for shipment. It is said that this product can be kept indefinitely if stored in a dry, cool place. The whites of the eggs are put into small glass-bottomed trays about one foot square and placed on shelves in a room having a temperature of 105 to 130 F. After thorough drying, the material is broken up into small pieces or is sometimes powdered or reduced to crystal form resembling granulated sugar. The shells are sold in Germany for poultry food. It requires about seventy yolks to make one pound of the dried product and the whites of about 200 eggs to make a pound of the egg albumin. The price of the whole dried eggs is 31 cents a pound; of the albumin, 44, and of the yolks, 24 cents a pound. This industry in German China is said to be growing rapidly. If all that is claimed for it is true, this certainly should be a more satisfactory method of preserving eggs than that of cold storage. The difficulty, in this country at least, would be the lack of government supervision to insure that the eggs were fresh when utilized.

THE IRREPRESSIBLE CONFLICT

In 1858, William H. Seward, senior senator from New York, in describing the approaching struggle between two opposing conceptions of our national government, spoke of it as "the irrepressible conflict." His prophetic eye foresaw the coming storm. He saw, too, how impossible it was to prevent it. This phrase, caught up at once all over the nation, became one of the famous sayings of this strenuous period. The tendency of history to repeat itself has become proverbial. The present "investigation" of Dr. Wiley by the congressional committee affords another instance of a conflict just as important and irrepressible as that of fifty years ago. At the beginning of the hearing, the question at issue was whether or not Dr. Wiley had violated the law in the manner of employing an expert pharmacognosist. But this point has long ago been lost sight of. The committee and congress are now called on to determine whether the national Food and Drugs Act, won after years of struggle, shall be administered for the benefit of the people, or nullified for the profit of the manufacturers. Wiley and Bigelow and Kebler on the one hand, and Wilson, McCabe and Dunlap on the other, are but the representatives of the opposing interests. The real question is: Which is of greater importance, the health of the American people or the financial prosperity of certain business houses? This is the "irrepressible conflict" of to-day. It must be fought out to a finish and it must be settled aright. Which will triumph, the people or the interests? This is the real issue in the Wiley case.

HEALTH CAMPAIGN IN THE SOUTH

Ten thousand patients suffering from hookworm disease were treated in 107 days by one of the representatives of the Alabama State Board of Health with the help of three assistants, this work covering five counties of Alabama. In addition to treating the victims of the hookworm, the representatives of the state board of health are visiting the physicians, the school teachers and the schools, lecturing to public meetings, showing stereopticon views to demonstrate the cause and progress of the disease and the results of treatment, and using the country newspapers as a means of publicity for their work. The value of the Panama Canal as an object-lesson in modern sanitation has been frequently emphasized. The work now being done in the southern states for the elimination of hookworm disease will be an even greater demonstration of the economic value of modern medical science, when practically applied. The results of restoring to health ten thousand men and women cannot fail to be apparent in all branches of industry, commerce and society in the affected region. The extermination of the hookworm means a new South of commercial and manufacturing importance hitherto undreamed of. Health is wealth; sickness is waste, and no nation or section can prosper when the vitality of its people is being wasted.

Medical News

ALABAMA

Gift to Hospital.—Boston friends of the Tuskegee Institute have donated a hospital to the institute to be known as the "John A. Andrew Hospital." The donors do not desire to have their names made public.

Sanatorium Company Organized.—The Columbiana Sanatorium, Land and Improvement Company has been organized at Columbiana with Dr. Joel Chandler, Birmingham, as president. The company expects to erect a sanatorium and hotel.

Personal.—Dr. John D. S. Davis, Birmingham, is reported to be seriously ill with uremia in Colorado Springs.——Dr. William W. Haden, Huntsville, has been appointed health officer of Madison County, vice the late Dr. William C. Wheeler, Huntsville, to fill unexpired term.

Rotation in Office.—The Madison County Medical Society on August 8 adopted resolutions providing for rotation of the office of health officer in Madison County after the expiration of the present term. The vacancy is to be filled by the senior member of the society who, after a year's service, will resign in favor of the one next junior to him and so on down the line.

GEORGIA

Personal.—Dr. Floyd W. McRae, Atlanta, has sailed for Europe.——Dr. Walpole Brewer, after an absence of eight years in Tennessee and New York, has returned to Atlanta.

New State Journal in Georgia.—In line with the action of other states the Medical Association of the State of Georgia has begun the publication of a state journal as the official organ of the association. The first number appeared in August. It is under the editorial management of the board of councilors, of whom Dr. Wyman W. Pilcher, Warrenton, is chairman. It is issued from Augusta. The first number contains a number of interesting papers and discussions, the program and minutes of the 1911 state meeting, society reports, some editorial comments, personal items, book reviews, etc. It is a very creditable number, neat in its mechanical appearance, and should succeed.

MISSOURI

University Medical College to Continue.—It is announced that the University Medical College of Kansas City, which was reported to have closed its doors, is to be continued, but that it will give only the last two, or clinical years. It is stated that it will accept only students who have taken the first two years' work in medical schools having standards as high as those held by the University of Missouri Department of Medicine.

NEW YORK

Personal.—Dr. Ernest P. Livingston, New York City, sailed for Europe on August 12.——Dr. Claude A. Frink, New York City, has recently been appointed attending surgeon to the New York City Children's Hospitals and Schools.——Dr. Amos T. Baker, Fishkill-on-the-Hudson, assistant superintendent of the Matteawan State Hospital for the Criminal Insane, has resigned.

Milk Exhibit for State Fair.—The New York Milk Committee and the New York Dairy Demonstration Company have accepted an invitation from the State Commissioner of Agriculture to make an exhibit at the State Fair at Syracuse in September. The methods of producing pure milk for New York City will be shown. The milk committee will show by charts and literature what is being done all over the United States in establishing uniform standards of milk inspection, the proper relation between municipal and state authorities, and the need for interstate cooperation. There will be a reproduction of a city milk station and clinics and demonstrations will show what is being done to reduce infant mortality.

New York City.

Anterior Poliomyelitis.—The Rockefeller Institute of Medical Research announces its desire to receive and treat gratis acute cases of anterior poliomyelitis during the present summer and fall. In the event of any fatal case, if an autopsy is held, portions of the spinal cord, the nasal mucosa, tonsils and adenoids are asked for.

Sea Breeze.—Under the auspices of the Association for Improving the Condition of the Poor, 25,886 mothers and infants were given an outing at Sea Breeze last summer. Up to August 16, of this year, the association has sent 17,059 mothers and children to this resort, and of this number 3,000 stayed a week or longer.

Another Milk Station Opened.—The board of health has opened a fifteenth pure milk station in Division Street, one of the most congested sections of the city. In all of the stations to August 13, 10,844 babies were registered; there were twenty-nine deaths during the week ending August 12, the highest number recorded thus far in any one week.

Infant Death-Rate Lower.—The total number of infant deaths from January 1 to August 12, according to statistics of the health department, was 9,398 as compared with 10.365 for the same period of 1910. Dr. Lederle has issued a warning to those conducting the campaign in behalf of the babies and to parents reminding them that while the time of the highest mortality has passed there is often a "high" period in September and vigilance should not be relaxed.

Health Department Closes Bathhouses.—When the authorities closed the bathhouses on Flushing Bay, it was rumored that the action was taken because of the insanitary conditions and the existence of several cases of infantile paralysis in the neighborhood, but later it was learned that the real reason was that the bathhouses did not have proper sterilizing plants for the bathing suits and there were complaints that this had been the means of communicating disease.

Typhoid Fever and Infantile Paralysis Increase.—From August 1 to 12 there were reported to the health department 279 cases of typhoid fever against 191 for the same period last year. In the nine weeks ended August 12 there were 448 cases reported against 298 in the same period of 1910. While there seems to be no certainty as to the cause of the infection the department is inclined to attribute it to infected milk and the supply of milk from several localities has been stopped temporarily. Since the first of August sixteen cases of infantile paralysis have been reported to the health department while there were no cases reported at that time last year.

The Need of Better Statistics.—The relation between vital statistics and the public health is discussed in the monthly bulletin of the department of health. It has been found that the present system in New York City is inadequate and a committee was appointed by the department of health to consider the subject and to make a report. After pointing out the shortcomings of present methods and showing the many ways in which accurate vital statistics would be useful the report makes the following recommendations:

1. Divide the city for the purposes of tabulation into small sanitary districts, the boundaries of which should coincide wherever possible with those of the 708 40-acre tracts of the Census Bureau.
2. Tabulate the deaths, births and marriages in the city in 1910 and subsequent years by these tracts.
3. Establish a working agreement with the Census Bureau regarding the tabulation of deaths and births to be made by each, in order to avoid duplication.
4. Estimate the cost of producing each statistical table now published by the bureau, and consider whether the same amount of money might be made to yield a better return to the city by changing the character of the table.
5. In selecting subjects for statistical investigation emphasize those on which the attention of other divisions of the Department of Health is concentrated and those in regard to which public interest has been or can easily be aroused.
6. Plan to have the state enumeration of 1915 taken with reference to serving as a basis for the vital statistics of this city by adding to the schedule certain questions of local value, as has been done to great advantage in several foreign capitals.

The committee suggests that the name of the present Bureau of Records be changed to the Bureau of Vital Statistics and be organized in three divisions: Records, Research and

Publicity. The members of the committee framing the report are: Prof. Walter F. Wilcox of Cornell University, consulting statistician of the New York State Department of Health; Prof. C. E. A. Winslow of the College of the City of New York, formerly connected with the Massachusetts Institute of Technology; Dr. Cressy L. Wilbur, chief statistician of the Federal Department of Commerce and Labor, and Dr. Robert S. Tracy, who retired as register of records in the department of health in 1901, after thirty-one years' services. From the department of health, Dr. William H. Guilfoy, register of records, and Dr. Hermann M. Biggs, general medical officer, and Dr. S. Josephine Baker, director of the department of hygiene.

NORTH CAROLINA

New Public Hospital.—Winston-Salem has recently voted $100,000, secured by municipal bonds, to be used for the erection of a new public hospital.

Free Antitoxin for Caldwell County.—The commissioners of Caldwell County have instructed Dr. Charles B. McNairy, Lenoir, health officer, to keep on hand a supply of diphtheria antitoxin for those unable to pay for it.

Hookworm Dispensary Opened.—The hookworm dispensary at Scotland Neck was opened, July 27, with Dr. Platt W. Covington, Rockingham, in charge. During the day, 335 applications were received and about forty-eight cases of hookworm were found in the examination of less than one-half the applicants. More than thirty patients were placed under treatment. The dispensary is open every two weeks and at these times patients will be examined and if necessary will be given free treatment.

Personal.—Dr. James J. L. McCullers, McCullers, has been appointed superintendent of health of Wake County by the secretary of the State Board of Health, as the authorities of the county had failed to elect a superintendent as provided by law.——Dr. James M. Templeton, Carey, has been elected first vice-president of the National Farmers' Union of America.——Dr. Charles A. Woodard, Durham, has started for Europe.——Dr. Louis Booker, Charlottesville, Va., has been appointed assistant resident physician to the State Tuberculosis Hospital, Montrose.——The building occupied by Dr. Edward P. Snipes, Jonesville, was destroyed by fire, July 26.——Dr. Thomas A. Mann, health officer of Durham, has resigned. At the last meeting of the Durham Medical Society, resolutions commending the work done by Dr. Mann were unanimously adopted.

NORTH DAKOTA

State Board Elects.—At the annual meeting of the State Board of Medical Examiners held in Fargo, July 31, Dr. Paul Sorkness, Fargo, was elected president, and Dr. George M. Williamson, Grand Forks, secretary.

New Dean for Medical College.—Dr. Harley E. French, for four years professor of anatomy at the University of South Dakota, Vermilion, has been appointed dean of the faculty and professor of anatomy at the University of North Dakota, Grand Forks.

PENNSYLVANIA

Bequest.—The will of the late William Alexander Smith, for many years president and treasurer of the New York Stock Exchange, bequeaths $3,000 to the Pottstown Hospital.

Hospital Additions.—Work on the erection of a dispensary for the Medico-Chirurgical Hospital on Cherry Street, west of Seventeenth, was begun August 17. It is to be a one-story structure 59.7 by 146 feet and will cost $20,000.——St. Christopher's Hospital, Lawrence and Huntingdon Streets, is building a two-story addition at a cost of $1,000.

New Hospitals Opened.—The J. C. Blair Memorial Hospital Building, Huntingdon, completely equipped and furnished, was opened for inspection August 24, the physicians' and press day. After examination of the hospital, a buffet lunch was served and in the afternoon addresses were given by Drs. Francis P. Ball, Lock Haven, and Theodore L. Chase, Philadelphia, and a press representative. The public will be allowed to inspect the building from August 26 to August 30, and the hospital will be opened to receive patients September 4.

Typhoid on the Decrease.—According to the records of the bureau of health for the week ending August 19, there were ten deaths from typhoid fever, but the number of cases reported was fifty-six as compared with sixty-four for the preceding week. Of the present week's total, fourteen cases were reported from the Thirty-Second Ward and investigation by the inspectors of the health bureau showed that the cases were contracted from milk infection. The cause was traced to a dairy outside of the city and Chief Vogelson reported the result of the investigation to the State Health Commission and the dairy was closed.

Reduction of Tuberculosis Death-Rate.—Dr. Thomas H. A. Stites, chief of the division of dispensaries of the State Department of Health, in a paper read before the Sixteenth Censorial District Medical Society, held at Montrose, August 15, declared that Pennsylvania had the lowest death-rate from tuberculosis during 1910 of any of the five middle states. He stated that the average number of deaths during the year from all causes in the states of Maryland, Massachusetts, New York, Ohio and Pennsylvania was 408,050, of which 42,075, or 10.3 per cent. were due to tuberculosis. Pennsylvania reports the lowest percentage, 8.6 per cent. from this cause.

Reading Promises Refrigerator Service.—On August 10, the State Railroad Commission concluded a hearing of complaint against the Reading Railroad by a local milk dealer, who is seeking to compel that road to transport milk to the city in refrigerating cars, by deciding that no recommendations would be made until the producers and shippers of milk should have a hearing, and to accomplish this sent invitations to 2,000 milk producers within a radius of 60 miles of the city. In the meantime a conference was held between John F. Auch, general freight traffic manager of the Reading Railroad and a committee of the Interstate Milk Producers' Association and assurances were given by the railroad that refrigerator car service will be furnished to shippers of milk to Philadelphia, beginning next spring.

Freedom from Water Pollution.—The waters of the state of Pennsylvania under enforcement of the purity of water law in 1905 are being freed from pollution. Phoenixville, the last town on the Schuylkill, taking an unfiltered supply of water from that river, has now submitted plans for germicidal treatment of the water pending the submission of comprehensive plans for a modern filtration plant. Lebanon has prepared plans for a sanitary system of sewers and sewage treatment plant and has appropriated funds for the construction of these improvements. Plans have also been drawn for a complete sanitary sewerage system and treatment plant for the borough of Middletown. In Lancaster, extension of the water filter plant are necessary on account of the increasing population of that city. Ligonier has been compelled to build a sewage treatment plant and its work is now in progress. Sunbury has been refused permission to extend its sewers until prior decrees of the commission of health which ordered sanitary improvements, have been obeyed. Jersey Shore is to have a new pumping station and intake, germicidal treatment of the water and a large storage reservoir. Lock Haven is also about to build a new dam and a large storage reservoir. Renovo, which owns its own water works and sewer systems, is extending and improving both. Palmerton, the headquarters of the Pennsylvania Zinc Company, is enlarging the sewage treatment plant and extending sewers in accordance with plans approved by the department. Danville has submitted plans for a complete sanitary sewer system and for sewage treatment work which has been approved by the State Department of Health. The Muncy Water Company has been cited to show cause why its charter should not be taken away on complaint of the commissioner of health unless forthwith it treats its water temporarily and installs at the earliest moment a modern filter plant. The borough of New Brighton and a chain of municipalities stretching along the banks of the Beaver River have been ordered to provide for an outfall sewer and ultimately for a sewage disposal plant. Harrisburg is expending this season $500,000 for improved sewerage work to take the sewage out of the river all through the major length of the city along the banks of the Susquehanna.

GENERAL NEWS

Unauthorized Subscription Agencies.—THE JOURNAL has repeatedly published warnings against paying money to unauthorized persons who pretend to take subscriptions. All agents of THE JOURNAL who are authorized to receive money carry signed and sealed current letters of identification on the Association stationery. Physicians write of having paid money to the Seattle Subscription Company, Seattle, Wash., and to J. R. Russell of the Twin City Magazine Company, St. Paul, Minn. They receive receipts, but that seems to be all that they receive for the money as none of it is sent to the periodicals for which subscriptions are taken. THE JOURNAL called attention to the Seattle Company not long ago when a man was operating under that name in Montana. It seems that he has been working east and that physicians are still careless about their money.

The Christian A. Herter Memorial Fund.—In the *Journal of Biological Chemistry*, August, 1911, appears an announcement of The Christian A. Herter Memorial Fund. This fund, now amounting to $40,000, has been confided to the care of the directors of the *Journal of Biological Chemistry* under the provisions of a declaration of trust executed by them. The chief aim of the trust is to further the interests of the *Journal of Biological Chemistry*, an instrument for the development of science created by Christian A. Herter and fostered by him up to the time of his death. In the event that conditions arise removing the need for such a use of the income, provisions are made by which the fund shall continue as a memorial of Professor Herter and of service to humanity by the promotion of scientific research. Dr. Simon Flexner, New York, is the president and Dr. A. N. Richards, Philadelphia, the secretary of the directory in charge of the fund.

FOREIGN NEWS

Dr. Herbert Timbrell Bulstrode, medical inspector to the local government board and lecturer on preventive medicine at Charing Cross Hospital Medical School, London, died suddenly at his home in London, July 21, aged 52. Dr. Bulstrode was an arduous and painstaking worker, and the first fruit of his important work was the Milroy lectures delivered in London, before the Royal College of Physicians in 1903, on "*The Causes, Prevention and Control of Pulmonary Tuberculosis.*" He was next commissioned to make especial enquiry into the sanatorium treatment of tuberculosis, the result being the "Sanatoria for Consumption," published by the local government board. His next most important work in the line of preventive medicine was on the spread of diseases by shellfish, and as a result of his revelations, no doubt is left as to the necessity of legislative action prohibiting the sale of shellfish from contaminated sources.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, Aug. 12, 1911.

Remarkable Improvement in the Health of London

A remarkable improvement in the public health of London is shown by a recent report issued by the government. During the past year the general death-rate was 13.7; the death-rate from consumption was 1.2; and the number of infant deaths per thousand births was 103. Contrasting these figures with the average for the years 1901-5, the general death-rate was 17; the death-rate from consumption, 1.6, and the infantile death-rate, 139. Thus, the general death-rate has declined 19 per cent.; the death-rate from consumption, 25 per cent., and the infantile death-rate, 26 per cent. A similar improvement is shown in regard to infectious diseases. The number of cases of scarlet fever in the past year was 10,509, of diphtheria 5,494, of typhus 3, and of typhoid fever 1,284. The corresponding figures for the average of the years 1901-5 were 10,509, 8,865, 12 and 2,478. The only disease which has shown some increase is measles. The great improvement in the infantile death-rate is due to the increased regard for infantile hygiene, which is largely the result of the work of "health visitors." The precautions against importation of exotic disease have never been more successfully carried out than at present; although both cholera and plague have from time to time appeared in the Port of London, the infection has never spread. Although, as mentioned in a previous letter to THE JOURNAL, plague rats were found at Wapping, a higher point on the river than ever before, the disease has not spread to man.

Lunacy in England and Wales

The statistics of lunacy for 1910 which have just been issued show that there were 2,604 more certified insane persons in England and Wales at the end of the year than on the corresponding date of the previous year. The corresponding increase for 1909 was 1,766, for 1908 2,703, and for 1907 2,096. For the decennium ending 1910 the average increase was 2,521. Extending the survey backward a continuous increase in insanity is shown. Thus, since 1869 the population has increased by 64.6 per cent., while the number of insane has increased by 150.4 per cent. In 1869 the ratio of the insane to the population was 23.92 per 10,000; on Jan. 1, 1911, the ratio had risen to 36.4. From these figures the conclusion might be drawn that for many years insanity has been increasing. However, the commissioners on lunacy, who issue these reports, say: "The increase in the number of insane recorded year by year is no proof of an actual growth of insanity in the community, although it is often assumed to be such. Such facts as are available tend to the conclusion that if insanity is increasing at all it is doing so very slowly and by no means proportionately to the increasing numbers of insane persons under care." The figures are explained by an increasing accuracy in the diagnosis of insanity and a greater readiness to send patients to asylums, who otherwise would remain uncertified. There is a most interesting discussion in the report of the inheritance of insanity. It is estimated that there are about three insane persons who apparently come from insane stock, for every one with a family history of insanity. But the commissioners insist that these figures cannot be used to minimize the importance of inheritance. They point out that the question is much more complicated. There may be a family history—and, in fact, there are many such histories—in which no positive insanity can be traced, but in which there are evidences of instability of the nervous system due to a large variety of causes, of which alcohol is one of the most important. This instability may manifest itself in many directions apart from actual insanity.

Pharmacists and Secret Remedies

The annual meeting of the British Pharmaceutical Conference has just taken place at Portsmouth. A very important discussion took place on the subject of secret and proprietary medicine. A report was submitted giving the answers received by the conference, to a series of questions addressed to eighty-eight local associations of pharmacists in all parts of the United Kingdom. They all agreed that the sale of secret and proprietary medicines by pharmacists is considerable. Eighty-six per cent. stated that proprietary articles are ordered by doctors in their respective districts to a considerable extent, and of these 20 per cent. reported such ordering to be by verbal recommendation, 20 per cent. by prescription, and 60 per cent. in both ways. In reply to the question, "Would you regard with favor proposals for legislation making compulsory a declaration on the label of all the principal ingredients"? 70 per cent. replied in the affirmative, 24 per cent. in the negative and 6 per cent. were doubtful; 88 per cent. were of the opinion that such legislation would curtail the sale of undesirable quack medicines. In regard to the prescribing of proprietary articles by doctors, the suggestion was frequently made that much greater use should be made of the British Pharmaceutical Codex in prescribing. The discussion was opened by Mr. E. F. Harrison, who referred to the usual mendacious advertisements by which quack medicines were sold. He regarded the great majority of secret remedies having a large sale as possessing a certain usefulness in some of the disorders for which they were recommended, but as frequently advertised by grossly exaggerated and untrue statements. He moved the following important resolution which after discussion was carried unanimously: "That this meeting of the British Pharmaceutical Conference is of opinion that a public inquiry, by a royal commission, a select parliamentary committee or a departmental committee, should be held in regard to the advertising and sale of proprietary secret medicines and the law relating thereto, with a view to further legislation for the prevention of fraud and quackery."

The Plague in India

In his speech on the Indian budget the under-secretary for India made an important announcement on the subject of plague. He thought there was urgent need for the education of the masses of India in the principles of hygiene. Though archaic habits might be tolerable in the open country, when transferred to the crowded town they became unsupportable. If there were less ignorance and less perversity, plague would never have found the lodgement it had. Persons living under proper sanitary conditions were virtually exempt. Plague did not attack the jail population or the native army; it attacked the ordinary civil population because they lived in houses which were not rat-proof and because they treated the rat almost as a domestic animal and refused to kill it. Plague had now been present in India for fifteen years, and the deaths from it had reached the appalling total of 7,500,000. Of this, the Punjab accounted for nearly 2,500,000. In the last ten years, 11 per cent. of the population of that province had died from plague. The vaccine discovered by Professor Haffkine conferred a comparative, though not absolute, immunity for a time. But the unhappy accident at Mulkowal, where several villagers died of tetanus after inoculation gave the treatment a blow from which it has never recovered. The disease was now largely fought by house evacuation, which was easier in villages than towns. Special plague doctors and subordinates were appointed. When plague occurred they visited the locality, offered inoculation and gave assistance to persons to vacate their houses. An improvement in the general sanitary condition of the people had taken place and was being promoted by grants from the government.

The Compulsory Segregation of the Subjects of Venereal Disease

An influential deputation, among whom were eminent members of the profession interested in questions of public health —Sir Victor Horsley, Sir James Crichton-Browne, Dr. F. W. Mott—has presented to the president of the local government board, Mr. John Burns, a petition urging that effect should be given by detention or some form of compulsory treatment, to the recommendation of the royal commission on the poor laws, for the detention in poor-law institutions of persons suffering from venereal disease, when medically certified to be dangerous to others. The petition was signed by a number of well-known ladies representing various associations engaged in philanthropic work, physicians and members of town and borough councils. Sir Victor Horsley and Dr. Mott supported the petition from the medical standpoint and Lord Kinnaird, chairman of the committee of the Lock Hospital, spoke as a life-worker among young men. Mr. Burns in reply quoted figures showing a marked diminution in venereal disease during recent years, and while holding out no hope of legislation empowering detention, assured the deputation that he would by administrative action do all in his power to promote the cure and stay the progress of venereal disease.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, August 4, 1911.

Suture of the Abdominal Aorta
